After the observation of time-dependent CP-violating asymmetries in the decays of neutral B mesons to CP eigenstates containing charmonium [1,2], it is interesting to extend the search for CP-violating effects to Cabibbo-suppressed double charm modes, such as $B^0 \rightarrow D^{(*)+} D^{(*)-}$ [3]. The interference of the dominant tree amplitude with the mixing diagram is sensitive to the angle $\beta$ of the unitarity triangle in this case as well; however, the theoretically uncertain contribution of penguin amplitudes with different weak phases is potentially significant and may shift the observed asymmetry by an amount that depends on the ratio of the penguin and tree contributions and their relative weak phases. The $B^0 \rightarrow D^{(*)+} D^{(*)-}$ vector-vector final state has very clear experimental signatures that make it an interesting candidate for CP-violation measurements. However, it is not a pure CP eigenstate and a dilution of the measured asymmetry can be produced by a $P$-wave, CP-odd, component. A time-dependent angular
The decay modes of $D^0$ and $D^+$ are selected by an optimization of $S^2/(S + B)$ based on Monte Carlo simulations, where $S$ and $B$ are the expected number of signal and background events, respectively. We first determine, based on Monte Carlo simulations, the expected $S - B$ for each of the decay mode combinations individually. Then, we successively add modes in order of decreasing $S - B$ to compute an overall $S^2/(S + B)$ value until $S^2/(S + B)$ no longer increases. The decay modes used are $D^0 \to K^- \pi^+$, $D^0 \to K^- \pi^- \pi^0$, $D^0 \to K^- \pi^- \pi^+ \pi^−$, $D^0 \to K^{0 \ast}_L \pi^- \pi^+$, $D^+ \to K^- \pi^- \pi^+$, $D^+ \to K^0 \pi^+ \pi^−$, and $D^+ \to K^+ K^- \pi^+$. $D^0 (D^+)$ meson candidates are required to have a reconstructed invariant mass within 20 MeV/$c^2$ of the nominal $D^0 (D^+)$ mass [9].

Charged kaon candidates are required to be inconsistent with the pion hypothesis, as inferred from the Cherenkov angle measured by the DIRC and the ionizations measured by the SVT and DCH. No particle identification is required for the kaon from the decay $D^0 \to K^- \pi^+$. $K^{0 \ast}_L \to \pi^+ \pi^- \pi^−$ candidates are required to have an invariant mass within 15 MeV/$c^2$ of the nominal $K_0^L$ mass. The angle between the flight direction and the momentum vector of the $K^{0 \ast}_L$ candidate is required to be less than 200 mrad, and the transverse flight distance from the primary event vertex, obtained from the remaining charged tracks in the event, must be greater than 2 mm.

Neutral pion candidates are formed from pairs of photons in the EMC with energy above 30 MeV, an invariant mass within 35 MeV/$c^2$ of the nominal $\pi^0$ mass, and a summed energy greater than 200 MeV. A mass-constrained fit is applied to these $\pi^0$ candidates. In the case of the soft $\pi^0$ from $D^{*+} \to D^+ \pi^0$ decays, the energy cut is replaced by a momentum cut, in the $Y(4S)$ frame, of $70 < p^* < 450$ MeV/$c$.

To select $B^0$ candidates with well-reconstructed $D^{*+}$ and $D$ mesons, we form a $\chi^2$ that includes all measured $D^{*+}$ and $D$ masses:

$$
\chi^2_{\text{mass}} = \left(\frac{m_D - \hat{m}_D}{\sigma_{m_D}}\right)^2 + \left(\frac{m_{\overline{D}} - \hat{m}_{\overline{D}}}{\sigma_{m_{\overline{D}}}}\right)^2 + \left(\frac{\Delta m_D - \hat{\Delta m}_D}{\sigma_{\Delta m_D}}\right)^2 + \left(\frac{\Delta m_{\overline{D}} - \hat{\Delta m}_{\overline{D}}}{\sigma_{\Delta m_{\overline{D}}}}\right)^2, \tag{1}
$$

where the caret over a value refers to the nominal value, and $\Delta m_{D^0}$ is the $D^{*+} - D$ mass difference. For $\sigma_{m_D}$ we use values computed for each $D$ candidate, while for $\sigma_{\Delta m_D}$ we use fixed values of 0.83 MeV/$c^2$ for $D^{*+} \to D^+ \pi^+$ and 1.18 MeV/$c^2$ for $D^{*+} \to D^+ \pi^0$. A requirement that $\chi^2_{\text{mass}} < 20$ is applied to all $B^0$ candidates. In events with more than one $B^0$ candidate, we choose the candidate with the lowest value of $\chi^2_{\text{mass}}$.

A meson candidate is characterized by two kinematic variables: the energy-substituted mass,

$$
m_{ES} \equiv \sqrt{E_{\text{beam}}^2 - p_B^2}, \tag{2}
$$
and the difference of the $B$ candidate’s energy from the beam energy,

$$\Delta E = E_B^* - E_{\text{beam}}^*, \quad (3)$$

$E_B^*$ ($p_B^*$) are the energy (momentum) of the $B$ candidate in the center-of-mass frame and $E_{\text{beam}}^*$ is one-half of the total center-of-mass energy. The signal region in the $\Delta E$ vs $m_{\text{ES}}$ plane is defined to be $|\Delta E| < 25$ MeV and $5.273 < m_{\text{ES}} < 5.285$ GeV/$c^2$. Based on Monte Carlo simulations, the width of this region corresponds to approximately $\pm 2.5 \sigma$ in both $\Delta E$ and $m_{\text{ES}}$.

To determine the expected contribution from background in the signal region, we scale the number of events seen in a sideband in the $\Delta E$ vs $m_{\text{ES}}$ plane defined as $|\Delta E| < 200$ MeV, $5.20$ GeV/$c^2 < m_{\text{ES}} < 5.26$ GeV/$c^2$ and $50$ MeV $< |\Delta E| < 200$ MeV, $5.26 < m_{\text{ES}} < 5.29$ GeV/$c^2$. The scaling factor is calculated by parametrizing the shape of the background in the $\Delta E$ vs $m_{\text{ES}}$ plane as the product of an ARGUS function $[10]$ in $m_{\text{ES}}$ and a first-order polynomial in $\Delta E$. Based on this parametrization we estimate that the ratio of the number of background events in the signal region to the number of events in the sideband region is $(1.72 \pm 0.10) \times 10^{-7}$. The uncertainty is derived from the observed variation of this ratio under alternative assumptions for the background shape in $m_{\text{ES}}$ and $\Delta E$ using Monte Carlo simulations. The simulations also indicate that there are no significant sources of background appearing in the signal region beyond that indicated by the sideband extrapolation.

After all selection criteria, 38 events are located in the signal region, with 363 events in the sideband region. The latter, together with the scaling factor determined above, implies an expected number of background events in the signal region of $6.24 \pm 0.33(\text{stat}) \pm 0.36(\text{syst})$. The systematic uncertainty comes from the background shape variation mentioned previously. Figure 1 shows a projection of the data on the $m_{\text{ES}}$ axis after requiring $|\Delta E| < 25$ MeV.

We use a Monte Carlo simulation of the BABAR detector to determine the efficiency for reconstructing the signal. The efficiencies range from 17.4% to 2.7%, depending on the $D$ decay modes. This, together with the total number of neutral $B$ mesons produced during data collection, allows us to determine the branching fraction for $B^0 \to D^{*+} D^{*-}$ to be

$$\mathcal{B}(B^0 \to D^{*+} D^{*-}) = [8.3 \pm 1.6(\text{stat}) \pm 1.2(\text{syst})] \times 10^{-4}.$$

The high charged particle multiplicity makes this measurement particularly sensitive to the tracking system. Therefore the dominant systematic uncertainty comes from our level of understanding of the charged particle tracking efficiency. Systematic errors are assigned on a per track basis for $\pi$, $K$, and soft $\pi$, and are added linearly (9.9%). The effect on acceptance due to the imprecisely known partial-wave content of the $B^0 \to D^{*+} D^{*-}$ final state is another source of potential systematic bias (6.6%). Other significant potential systematic biases arise due to the uncertainties on the branching fractions $[9]$ of the $D^{*+}$, $D^0$, and $D^*$ (5.6%) and the uncertainties in mass resolutions of reconstructed mesons (4.1%). The total systematic uncertainty from all considered sources is 15%.

In addition to the branching fraction quoted above, we have also measured the $CP$-odd fraction of the final state. This fraction, $R_\perp$, is determined from the angular distribution of the soft pions in the decay, analyzed in the transversity basis $[4]$. In this reference frame, three decay amplitudes determine the distribution of three decay angles. Integrating over time, $B$ flavor, and two of these three angles yields the following expression:

$$\frac{1}{\Gamma} \frac{d\Gamma}{d\cos\theta_\pi} = \frac{3}{4} (1 - R_\perp) \sin^2\theta_\pi + \frac{3}{2} R_\perp \cos^2\theta_\pi. \quad (4)$$

Here $\Gamma$ is the decay rate and $\theta_\pi$ is the angle between the normal to the $D^{*+}$ decay plane and the line of flight of the soft pion from the $D^{*+}$ evaluated in the $D^{*+}$ rest frame.

We perform an unbinned maximum likelihood (ML) fit to the 38 events in the signal region described previously. The fit takes into account the presence of background, whose properties are derived from the sideband sample, and the angular resolution $\sigma_\theta$ estimated from Monte Carlo.
simulations. We define the likelihood function to be

\[ \mathcal{L} = \prod_{i=1,n} \mathcal{L}_i \]

\[ = \prod_{i=1,n} [p \times \mathcal{F} (\theta_{u,i}, \sigma_{\theta,i}, R_{\parallel}^{\text{sig}}) + (1 - p) \times \mathcal{F} (\theta_{u,i}, \sigma_{\theta,i}, R_{\parallel}^{\text{bkg}})], \tag{5} \]

where \( n \) is the number of selected events. The contribution to the total likelihood from the \( i \)th event, \( \mathcal{L}_i \), is defined in terms of the purity, \( p \), of the sample and the probability density functions \( \mathcal{F} (\theta_{u,i}, \sigma_{\theta,i}, R_{\parallel}) \) for the signal and background. \( R_{\parallel}^{\text{sig}} \) and \( R_{\parallel}^{\text{bkg}} \) are the parameters describing the shapes of the signal and background angular distributions, respectively, and \( \theta_{u,i} \) is the measured transversity angle in event \( i \). The probability density functions \( \mathcal{F} \) are obtained from the convolution of the angular distribution [Eq. (4)] with Gaussian resolution functions describing the measurement uncertainties \( \sigma_{\theta,i} \). From studies of simulated data, \( \sigma_{\theta} \) was measured to be 0.11 (0.12) radians for charged (neutral) slow pions. A 10% uncertainty of these values is considered when estimating the corresponding systematic error.

The value of \( R_{\parallel}^{\text{bkg}} \) is evaluated by fitting the 363 events in the sideband region and setting \( p = 0 \) in Eq. (5). The result of this fit is \( R_{\parallel}^{\text{bkg}} = 0.29 \pm 0.04 \), compatible with the value expected for a uniform distribution (\( R_{\parallel} = 1/3 \)). To determine \( R_{\parallel}^{\text{sig}} \), we fit the 38 events in the signal region with \( R_{\parallel}^{\text{bkg}} \) fixed to 0.29 and \( p \) fixed at 83.6%. The result of the fit to the signal region, without the correction for angular acceptance bias described below, is \( R_{\parallel}^{\text{sig}} = 0.25 \pm 0.18 \text{(stat)} \), and is shown in Fig. 2. The probability of obtaining a lower likelihood, evaluated using a Monte Carlo technique, is 66%.

It should be noted that Eq. (4) is the differential decay rate \( \Gamma \) integrated over the full ranges of the other two decay angles in the transversity basis, neglecting any bias in the projected \( \theta_{\parallel} \) distribution introduced by detector acceptance effects. A detailed study of the kinematics of the decay shows that the incomplete detector coverage of the polar angle with respect to the beam axis does not introduce any bias in the distributions of the decay angles in the transversity basis. However, an inefficiency in detecting soft pions below a threshold in transverse momentum may indeed introduce such a bias due to the correlations between the decay angles and particle momenta in the laboratory frame. The amount of these acceptance losses depends on the population of phase space, determined by the values of the decay amplitudes.

An accurate correction for these acceptance effects requires the complete determination of the decay amplitudes using a full angular analysis on a sufficiently large data sample. To estimate the size of the acceptance bias on \( R_{\parallel} \) without knowing the decay amplitudes, the fit procedure was tested on several samples of \( B^0 \rightarrow D^{*+} D^{*-} \) simulated events generated with different sets of decay amplitudes. The different amplitudes affect, to varying extents, the correlated soft pions' transverse momenta and angular distributions. The fitted \( R_{\parallel} \) values were found to be consistent with the generated values in the limit of negligible soft pion inefficiency. Depending on the mix of decay amplitudes, they did reveal a bias once the pion-detection threshold was taken into account. Considering the full possible range of decay amplitudes, the calculated bias on \( R_{\parallel} \) ranged from \(-0.048 \) to \(+0.004 \). The central value of this interval is taken as a correction to the fitted \( R_{\parallel}^{\text{sig}} \), while its half width is taken as an estimate of the corresponding systematic uncertainty (0.026). Additional, smaller systematic uncertainties affecting the \( R_{\parallel} \) measurement arise from the imperfect knowledge of the resolution in the transversity angle \( \theta_{\parallel} \) (0.006), the angular distribution of the background (0.008), and the purity of the signal sample (0.0003). The total systematic uncertainty on \( R_{\parallel} \) is determined to be 0.028, giving the final corrected result:

\[ R_{\parallel} = 0.22 \pm 0.18 \text{(stat)} \pm 0.03 \text{(syst)} \].

In summary, we have observed a signal of \( 31.8 \pm 6.2 \text{(stat)} \pm 0.4 \text{(syst)} \) events in the decay \( B^0 \rightarrow D^{*+} D^{*-} \). Our measurement of the branching ratio is
\[ \mathcal{B}(B^0 \to D^{*+}D^{*-}) = [8.3 \pm 1.6(\text{stat}) \pm 1.2(\text{syst})] \times 10^{-4}. \]

From the transversity angular distribution of these events, we have also measured the \( CP \)-odd fraction, \( R_\perp \), of the final state. These measurements provide a starting point for measuring time-dependent \( CP \)-violating asymmetries in these decays when more data become available.

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues, and for the substantial dedicated effort from the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and kind hospitality. This work is supported by DOE and NSF (USA), NSERC (Canada), IHEP (China), CEA and CNRS-IN2P3 (France), BMBF (Germany), INFN (Italy), NFR (Norway), MIST (Russia), and PPARC (United Kingdom). Individuals have received support from the A.P. Sloan Foundation, Research Corporation, and Alexander von Humboldt Foundation.
