In July 2012, the ATLAS and CMS collaborations reported the discovery of a new particle [1,2] whose measured couplings and properties are compatible with the standard model Higgs boson (H) [3–6]. However, several extensions to the standard model—in particular, models featuring an extended Higgs sector [7–13]—predict new scalar resonances below or above the H mass which may be narrow when their branching ratio to two photons is non-negligible.

This Letter presents a search for a scalar particle X of mass m_X decaying via narrow resonances into two photons. It extends the method developed for the measurement of the H couplings in the H → γγ channel [3] to the range 65 < m_X < 600 GeV. Analytical descriptions of the signal and background distributions are fitted to the measured diphoton invariant mass spectrum m_{γγ} to determine the signal and background yields. The result is presented as a limit on the production cross section times the branching ratio of a scalar boson 

\[ \frac{\text{BR}(X \rightarrow γγ)}{\text{BR}(H \rightarrow γγ)} ] \]

restricted to a fiducial volume where the reconstruction efficiency is approximately independent of the event topology. The upper limits set extend over a considerably wider mass range than previous searches.

Search for Scalar Diphoton Resonances in the Mass Range 65–600 GeV with the ATLAS Detector in pp Collision Data at \( \sqrt{s} = 8 \) TeV

G. Aad et al.*

(Received 25 July 2014; published 20 October 2014)

A search for scalar particles decaying via narrow resonances into two photons in the mass range 65–600 GeV is performed using 20.3 fb\(^{-1}\) of \( \sqrt{s} = 8 \) TeV pp collision data collected with the ATLAS detector at the Large Hadron Collider. The recently discovered Higgs boson is treated as a background. No significant evidence for an additional signal is observed. The results are presented as limits at the 95% confidence level on the production cross section times branching ratio into two photons, in a fiducial volume where the reconstruction efficiency is approximately independent of the event topology. The upper limits set extend over a considerably wider mass range than previous searches.
to be smaller than 6 GeV, where $E_T^{\text{iso}}$ is defined as the sum of transverse energies of the positive-energy topological clusters [20] within a cone of size $\Delta R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} = 0.4$ around the photon candidate. The core of the photon shower is excluded, and $E_T^{\text{iso}}$ is corrected for the leakage of the photon shower into the isolation cone. The contributions from the underlying event and pileup are subtracted using the technique proposed in Ref. [21] and implemented as described in Ref. [22]. In addition, the background with dominantly photon ($\gamma\gamma$) component of the DY and Z boson is subtracted using the technique proposed in Ref. [21] and corrected for the leakage of the photon shower into the isolation cone.

The $m_{\gamma\gamma}$ invariant mass is evaluated using the leading photon ($\gamma_1$) and subleading photon ($\gamma_2$) energies measured in the calorimeter, the azimuthal angle $\Delta \phi$ and the pseudorapidity $\Delta \eta$ separations between the photons determined from their positions in the calorimeter, and the position of the reconstructed diphoton vertex [3].

After selection, the data sample consists of a continuum background with dominantly $\gamma\gamma$, $\gamma$-jet, and jet-jet events and Drell–Yan (DY) production of electron pairs where both electrons are misidentified as photons. Two peaking backgrounds arise from the Z boson component of the DY and from $H \rightarrow \gamma\gamma$.

To increase the sensitivity, the search is split into two analyses: a categorized low-mass analysis covering the range $65 < m_X < 110$ GeV and an inclusive high-mass analysis covering $110 < m_X < 600$ GeV. To provide sidebands on both sides of the tested mass point $m_X$, the $m_{\gamma\gamma}$ ranges are wider than the $m_X$ ranges probed and overlap at the transition between the two analyses.

The low-mass analysis requires a precise modeling of the DY background, dominated by the Z boson resonance, where both electrons are misidentified as photons, mostly classified as converted photons. The loss of signal sensitivity is mitigated by separating the events into three categories with different signal-to-background ratios, according to the conversion status of the photon pair: two unconverted (UU), one converted and one unconverted (CU), or two converted (CC) photons. Table I shows the fractions of signal and DY events expected in each category.

In each category, the Z resonance shape is described by a double-sided Crystal Ball function [23]. Because of the limited size of the fully simulated $Z \rightarrow ee$ sample [25,26] where both electrons are misidentified as photons, the shape parameters are determined by a fit to a dielectron data sample, where both electrons are required to fulfill shower shape identification criteria and the same $E_T$ thresholds as the photons.

Since most of the electrons misidentified as photons underwent large bremsstrahlung, the invariant mass distribution of the Z boson reconstructed as a photon pair is wider and shifted to lower masses by up to 2 GeV with respect to the Z boson mass reconstructed as an electron pair. The $Z \rightarrow ee$ invariant mass distributions extracted from data in each category are transformed by applying $E_T$-dependent shifts and smearing factors to the electron $E_T$ and $\phi$, to match the kinematics of the electrons misidentified as photons. Two sets of transformations are derived for $\gamma_1$ and $\gamma_2$ depending on their conversion status, using a $Z \rightarrow ee$ sample generated with POWHEG [27,28], interfaced with PYTHIA8 [29] for showering and hadronization. Figure 1 illustrates the effect of the electrons’ transformations on the invariant mass shapes in the fully simulated $Z \rightarrow ee$ sample. Systematic uncertainties on the template shapes and the Z peak position are evaluated by varying the parameters of the electrons’ transformations by $\pm 1\sigma$.

The DY normalization is computed from the $e \rightarrow \gamma$ fake rates, defined as the ratios of $e\gamma$ to $ee$ pairs measured in $Z \rightarrow ee$ data, separately for $\gamma_1$ and $\gamma_2$ and each conversion status. A correction factor obtained from fully simulated $Z \rightarrow ee$ events is applied to account for additional effects, mainly the differences in isolation efficiencies and vertex reconstruction efficiency between $\gamma\gamma$ and $ee$ events. The associated uncertainties (9% to 25%) are dominated by the

### TABLE I. Number of diphoton events in data ($N_{\text{data}}$), number of expected Drell–Yan events ($N_{\text{DY}}$), fractions of expected signal ($f_X$), and Drell–Yan ($f_{\text{DY}}$) in each conversion category for the low-mass analysis. The signal fraction is given for $m_X = 90$ GeV but the mass dependence is negligible.

FIG. 1 (color online). Invariant mass distributions in the CC category for fully simulated $Z \rightarrow ee$ events reconstructed as $ee$ (dotted lines), reconstructed as $\gamma\gamma$ (squares), and reconstructed as $ee$ after transforming the electrons to match the kinematics of the electrons misidentified as converted photons (circles).
The determination of the analytical form of the continuum background and the corresponding uncertainties follow the method detailed in Ref. [1]. The sum of a Landau distribution and an exponential distribution is used over the full \( m_{\gamma\gamma} \) range. The bias on the signal yield induced by the analytical shape function is required to be lower than 20% of the statistical uncertainty on the fitted signal yield for the background-only spectrum. This bias is measured from a large sample generated from a parametrized detector response and is accounted for by a mass-dependent uncertainty. Figure 2 shows background-only fits to the data in the low-mass analysis for the three conversion categories.

In the high-mass analysis, relative cuts \( E_{T}^{\ell} / m_{\gamma\gamma} > 0.4 \) and \( E_{T}^{\ell} / m_{\gamma\gamma} > 0.3 \) are added to the selection requirements to reduce the continuum backgrounds and thereby increase the signal sensitivity. In total, 108 654 events with \( 100 < m_{\gamma\gamma} < 800 \) GeV are selected.

To determine the continuum background shape over this large mass range, an exponential of a second-order polynomial is fitted inside a sliding \( m_{\gamma\gamma} \) window of width \( 80 \cdot (m_{X} - 110 \text{ GeV}) / 110 + 20 \text{ GeV} \), centered on the mass point \( m_{X} \). The analytical shape and the fit window width are chosen to fulfill the signal yield bias criterion, as defined for the low-mass analysis, to minimize the statistical uncertainty on the background.

The expected invariant mass distribution of the narrow resonance signal \( X \) is also modeled with a double-sided Crystal Ball function in the mass range \( 65 \leq m_{X} \leq 600 \) GeV, using fully simulated \( ggF(X) \) samples generated as for \( H \), where \( H \) is replaced by a scalar boson with a constant width of 4 MeV. Polynomial parametrizations of the signal shape parameters as a function of \( m_{X} \) are obtained from a simultaneous fit to all the generated mass points \( m_{X} \), separately for the high-mass analysis and the three low-mass analysis categories. The signal shape parameters extracted from \( ggF(X) \) are compared to the other production modes: VBF, WH, ZH, and \( t\bar{t}H \); the bias on the signal yield due to the choice of \( ggF(X) \) shape is negligible. The systematic uncertainty on the signal shape due to the photon energy resolution uncertainty ranges from 10% to 40% as a function of \( m_{X} \) [3]. The systematic uncertainty on the \( X \) peak position due to the photon energy scale uncertainty is 0.6% [3].

The expected fiducial cross section \( \sigma_{\text{fid}} BR(X \rightarrow \gamma\gamma) \) includes an efficiency correction factor \( C_{X} \) through

\[
\sigma_{\text{fid}} BR(X \rightarrow \gamma\gamma) = \frac{N_{\text{data}}}{N_{MC}^{\text{MC}}} \text{ with } C_{X} = \frac{N_{\text{MC}}^{\text{MC}}}{N_{\text{MC}}}.
\]

The H background shape is modeled by a double-sided Crystal Ball function and normalized for \( m_{H} = 125.9 \) GeV [30,31] using the most up-to-date standard model cross-section calculations and corrections [34] of the five main production modes: gluon fusion (ggF), vector-boson fusion (VBF), Higgsstrahlung (WH, ZH), and associated production with a top quark pair (\( t\bar{t}H \)). The \( ggF \) and VBF samples [3] are simulated with the POWHEG generator interfaced with PYTHIA8. The \( WH, ZH, \) and \( t\bar{t}H \) samples [3] are simulated with PYTHIA8. Figure 3 shows background-only fits to the data in the high-mass analysis.

The fiducial cross section \( \sigma_{\text{fid}} BR(X \rightarrow \gamma\gamma) \) includes an efficiency correction factor \( C_{X} \) through

\[
\sigma_{\text{fid}} BR(X \rightarrow \gamma\gamma) = \frac{N_{\text{data}}}{N_{MC}^{\text{MC}}} \text{ with } C_{X} = \frac{N_{\text{MC}}^{\text{MC}}}{N_{\text{MC}}}.
\]

![FIG. 2 (color online). Background-only fits to the data (black dots) as functions of the diphoton invariant mass \( m_{\gamma\gamma} \) for the three conversion categories in the low-mass range. The solid lines show the sum of the Drell–Yan and the continuum background components. The dashed lines show the continuum background component only.](image1)

![FIG. 3 (color online). Background-only fits to the data (black dots) as functions of the diphoton invariant mass \( m_{\gamma\gamma} \) for the inclusive high-mass analysis. The solid line shows the sum of the Higgs boson and the continuum background components. The dashed line shows the continuum background component only.](image2)
where \( N_{\text{data}} \) is the number of fitted signal events in data, \( N_{\text{MC}}^{\text{reco}} \) the number of simulated signal events passing the selection criteria and \( N_{\text{MC}}^{\text{fid}} \) the number of simulated signal events generated within the fiducial volume. The fiducial volume, defined from geometrical and kinematical constraints at the generated particle level, is optimized to reduce the model dependence of \( C_X \) using fully simulated samples of the five \( X \) production modes to cover a large variety of topologies. The photon selection at generation level is similar to the selection applied to the data: two photons with \( E_T > 22 \) GeV and \( |\eta| < 2 \) are required; for \( m_X \) greater than 110 GeV, the relative cuts \( E_T^{\gamma_1}/m_{\gamma\gamma} > 0.4 \) and \( E_T^{\gamma_2}/m_{\gamma\gamma} > 0.3 \) are imposed. The particle isolation, defined as the scalar sum of \( p_T \) of all the stable particles (except neutrinos) found within a \( \Delta R = 0.4 \) cone around the photon direction, is required to be less than 12 GeV. The \( C_X \) factor is parametrized from the \( \text{ggF}(X) \) samples and ranges from 0.56 to 0.71 as a function of \( m_X \). Systematic uncertainties include the maximum difference between the \( C_X \) of the five production modes, the effect of the underlying event (U.E.) and pileup.

The statistical analysis of the data uses unbinned maximum likelihood fits. The DY and \( H \) shapes and normalizations are allowed to float within the uncertainties. In the low-mass analysis, a simultaneous fit to the three conversion categories is performed. Only two excesses with 2.1 \( \sigma \) and 2.2 \( \sigma \) local significances above the background are observed over the full mass range \( 65 \)–\( 600 \) GeV, for \( m_X = 201 \) GeV and \( m_X = 530 \) GeV, respectively. This corresponds to a deviation of less than 0.5 \( \sigma \) from the background-only hypothesis. Consequently, a 95% limit on \( \sigma_{\text{fid}} BR(X \rightarrow \gamma\gamma) \) is computed using the procedure of Ref. [1]. The systematic uncertainties listed in Table II are accounted for by nuisance parameters in the likelihood function. In the low-mass analysis, the dominant uncertainties are the DY normalization and the residual topology dependence of \( C_X \). In the high-mass analysis, the largest uncertainties arise from the energy resolution and the

theoretical uncertainty on the production rate of the standard model Higgs boson around 126 GeV.

The observed and expected limits, shown in Fig. 4, are in good agreement, consistent with the absence of a signal. The limits on \( \sigma_{\text{bg}} B(R(X \rightarrow \gamma\gamma)) \) for an additional scalar resonance range from 90 fb for \( m_X = 65 \text{ GeV} \) to 1 fb for \( m_X = 600 \text{ GeV} \). These results extend over a considerably wider mass range than the previous searches by the ATLAS and CMS collaborations [1,35], are complementary to spin-2 particles searches [36,37], and are the first such limits independent of the event topology.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions, without whom ATLAS could not be operated efficiently.
