Abstract

The phenotypic effect of some single nucleotide polymorphisms (SNPs) depends on their parental origin. We present a novel approach to detect parent-of-origin effects (POEs) in genome-wide genotype data of unrelated individuals. The method exploits increased phenotypic variance in the heterozygous genotype group relative to the homozygous groups. We applied the method to >56,000 unrelated individuals to search for POEs influencing body mass index (BMI). Six lead SNPs were carried forward for replication in five family-based studies (of ~4,000 trios). Two SNPs replicated: the paternal rs2471083-C allele (located near the imprinted KCNK9 gene) and the paternal rs3091869-T allele (located near the SLC2A10 gene) increased BMI equally (beta = 0.11 (SD), P < 0.0027) compared to the respective maternal alleles. Real-time PCR experiments of lymphoblastoid cell lines from the CEPH families showed that expression of both genes was dependent on parental origin of the SNPs alleles (P < 0.01). Our scheme opens new opportunities to exploit GWAS data of unrelated individuals to identify POEs and demonstrates that they play an important role in adult obesity.

Introduction

The effect of genetic variants on phenotypes may depend upon the parent from whom the variant was inherited [1,2]. Parent-of-origin effects (POEs) may arise through imprinting; mechanisms of which include cytosine methylation and histone deacetylation [2]. To date around 50 human genes are known to be imprinted and for most mammalian species less than 1% of the genome is imprinted [3]. One plausible explanation for this phenomenon is the parental conflict hypothesis, whereby both parents would like to maximize the influence of their genome on their offspring [4]. Current methods for detecting parent-of-origin effects rely on assigning parental ancestry to the inherited alleles. This is straightforward in linkage studies, which have identified potential POEs on type 2 diabetes, body mass index (BMI) [5,6], and alcohol intake [7–9]. However, only a very few of these findings have been replicated and the identified linkage peaks often span large chromosomal regions harbouring hundreds of genes, hence the causal gene or regulatory sequence is unknown. A notable exception is the work of Kong et al [1] who inferred parental origin through genealogy information and long-range phasing to subsequently test for POEs. This study identified six SNPs, four associated with risk of type 2 diabetes and the other two associated with each of breast cancer and basal-cell carcinoma.

Genome-wide association studies (GWASs) of unrelated individuals have very precisely identified a large number of genetic loci harbouring SNPs whose (alternative) allele counts associate with common traits. Since GWASs predominantly include unrelated individuals, the parental origin of the alleles cannot be determined, hence genetic effects influenced by the parental origin of the alleles are typically not considered. Here we present a novel approach that is able to detect POEs using genome-wide genotype data of unrelated individuals. We chose BMI as our target trait, due to previous findings [5,6] and the large available sample size. We report the discovery of two novel loci affecting BMI in a manner dependent on the parent-of-origin of the transmitted alleles.

Impact of the discovered variants

By combining the effect difference estimates ($\beta_M - \beta_P$) from the family-based studies and the marginal association effect sizes
SNPs in SLC2A10 and KCNK9 Exhibit Parent-of-Origin Effect on BMI

Author Summary

Large genetic association studies have revealed many genetic factors influencing common traits, such as body mass index (BMI). These studies assume that the effect of genetic variants is the same regardless of whether they are inherited from the mother or the father. In our study, we have developed a new approach that allows us to investigate variants whose impact depends on their parental origin (parent-of-origin effects), in unrelated samples when the parental origin cannot be inferred. This is feasible because at genetic markers at which such effects occur there is increased variability of the trait among individuals who inherited different genetic codes from their mother and their father compared to individuals who inherited the same genetic code from both parents. We applied this methodology to discover genetic markers with parent-of-origin effects (POEs) on BMI. This resulted in six candidate markers showing strong POE association. We then attempted to replicate the POE effects of these markers in family studies (where one can infer the parental origin of the inherited variants). Two of our candidates showed significant association in the family studies, the paternal and maternal effects of these markers were in the opposite direction.

\[(\beta_M + \beta_P)/2\] from the largest-to-date meta-analytic study on BMI [10], we estimated the effects of the maternal and paternal alleles. For both rs2471083-C and rs3091869-T we obtained \(\beta_M = -0.055\) and \(\beta_P = 0.055\). Using these effect sizes and the population frequency of these SNPs, we calculated the explained variance of these SNPs (if their parent of origin is known) to be 0.24% and 0.30% for rs2471083 and rs3091869, respectively. These effects are comparable to that of the strongest BMI-associated variant in the FTO gene (0.34%) [10].

Notably, rs2471083 is located 105 kb upstream of the imprinted gene KCNK9. Mutations in this potassium channel gene cause Birk-Barel syndrome, a maternally transmitted syndrome of mental retardation, hypotonia, and unique dysmorphism, resulting from genomic-imprinting [11]. SNPs within 2 kb have been shown to be associated with HDL cholesterol, adiponectin levels [12] and blood pressure [13]. Its impact on hypertension is potentially via a mechanism involving aldosterone, the concentration of which is increased in hypertension [13]. Its impact on hypertension is potentially via a mechanism involving aldosterone, the concentration of which is increased in hypertension [13].

We tested these two confirmed SNPs in 705 trios with paediatric (extreme) obese offspring in which parental origin of the alleles was known in up to 255 individuals [17]. No significant effect was observed (see Table S5). This could be due to insufficient power, different genetic mechanisms between young individuals and adults or that our association is specific to variations within the range of normal BMI.

Expression experiments

We evaluated whether the parent of origin effect of the rs2471083-T and rs3092611-T (proxy for rs3091869-T, \(r^2 = 0.998\)) alleles can be observed in the expression levels of their respective genes (KCNK9 or SLC2A10). To test this we carried out quantitative PCR (qPCR) experiments using lymphoblastoid cell lines (LCL) of the CEPH families. These cell lines have been used extensively to identify imprinted genes [18,19]. Using the available trio data we could infer the parental origin of the alleles of rs2471083 and rs3092611 in 33 populations (24 maternal T alleles, 24 paternal T alleles) and 24 (16 maternal T alleles, 8 paternal T alleles) individuals respectively (Table S7). We performed between 2 and 10 technical replicates per individual (mean of 7.75) and samples with high coefficient of variation (>5%) were discarded in order to ensure robustness. After quality control, 124 expression values from 25 (mat:pat = 4:19) samples for KCNK9 and 240 expression values from 24 (mat:pat = 16:8) for SLC2A10 were available for analysis. We fitted a linear mixed model to test for association between expression levels (Ct values) and allelic origin. The parental T allele of rs2471083 was associated with lower KCNK9 expression levels (P = 0.0096), and the paternal T allele of rs3092611 was associated with higher SLC2A10 expression values (P = 0.0023). To ensure there was no systematic bias in our experiments giving rise to spurious POE associations we repeated the qPCR experiments for two housekeeping genes GAPDH and HRPT1. Both analyses gave non-significant POE P-values (P > 0.3).

Methylation lookups

POEs can be driven by differences between inherited paternal and maternal methylation. To explore whether the observed parent-of-origin effects at our discovered SNPs were driven by differential methylation we tested whether methylation in the regions (Chr8: 140.4–140.65 Mb and Chr20: 45.3–45.55 Mb) was associated with the two respective SNPs (rs2471083, rs3091869) in 262 unrelated individuals from the TwinsUK cohort and (ii) associated with BMI in two independent cohorts: 79 BMI discordant (difference >0.5 SD) monozygotic twin pairs from the TwinsUK cohort and a sample of 412 unrelated individuals from the EPIC-Italy cohort. None of these analyses showed significant association (see Supplemental Data S1, Figures S2, S3 and Table S8 for further details).

Discussion

Our novel approach revealed two SNPs, located near the genes KCNK9 and SLC2A10, influencing BMI in a parent-of-origin specific fashion. These loci were the first and fourth most significant genome-wide in our new POE test for unrelated individuals and both showed significant parent-of-origin effects in family studies. Both SNPs exhibit polar overdominance, where homozygous individuals have equal (baseline) phenotypes and heterozygous individuals have equal (baseline) phenotypes and heterozygous genotypes confer relative risk/protection, depending on the parental origin. Parental overdominance, has been observed in humans for type2 diabetes [1] and BMI [20], however it is very rare and its molecular mechanism is unknown.

RT-PCR experiments revealed that gene expression levels of KCNK9 and SLC2A10 in LCLs were also influenced in a parent-of-origin manner. The expression of these genes is highest in the brain (although it is also expressed in tests, liver, colon, adrenal gland and kidney; see http://www.genecards.org/) indicating a potential neuronal involvement. Expression levels of KCNK9 and SLC2A10 in living brain cells might have been more informative and robust, however, such information is not available. The applied qPCR method was optimised to ensure that the expression levels measured in LCLs were representative only of the target transcript and amplification efficiency was assessed to be sensitive enough to allow the detection of even small changes in gene expression. Interestingly, rs2471083 alleles, regardless of their
parental origin, show marginally significant association (P = 0.03) with KCNK9 expression levels in the hippocampus (http://www.broadinstitute.org/gtex/). Our methylation analyses did not reveal any evidence that the POEs were driven by differences in inherited paternal and maternal methylation. Neither of our two SNPs tag common copy number variants (CNVs) (based on the CNV reference data used in Heid et al. [21]) and we found only one sample (out of 14,315 available in-house, whose BMI Z-score was +1.18) with a 76 kb deletion overlapping rs2471083. Hence, the effect of the two discovered SNPs are unlikely to be driven by CNVs. To check whether the two confirmed SNPs (rs3091869, rs2471083), or SNPs in LD (10 with $r^2$>0.8 in 1000 Genomes EUR population), show regulatory activity, we queried RegulomeDB (http://regulome.stanford.edu). None of these SNPs were annotated to have more than minimal binding evidence (RegulomeDB score below 4).

A previous study proposed to detect POE in inbred F2 mice by a two-component mixture distribution fitting of the heterozygous genotype group and further two components for the homozygous groups [22]. This method requires a parametric distribution of the phenotype to be assumed, small violations of this assumption can result in heavily biased parameter estimates. The method we chose is more robust to a wide range of phenotype distributions (due to the underlying Brown-Forsythe test employed), computationally faster (making it attractive for testing millions of SNPs) and applicable to probabilistic genotype calls. Our POE test for unrelated GWAS samples is similar to a test proposed to detect gene-environment interactions [23] in that it exploits differences in phenotypic variance to detect a phenomenon not directly measured. Inflated phenotypic variance in the heterozygous group might also be the result of other phenomenon: (i) a phenotype altering effect (be it genetic or environmental) acting only on the

Figure 1. Explanation of the POE test. Top panel illustrates the phenotype distributions in the four genotype groups that would be observed if the parent-of-origin of the alleles were known. Bottom panel shows how these distributions change if the parent-of-origin is unobserved. The resulting heterozygous group will have increased variance due to its heterogeneity. This example describes a scenario we observe for the two replicated hits, namely that the paternal- and maternal effects are of the same size, but opposite in direction ($\beta_M = -\beta_P$). Therefore the average phenotype in the B/B group is the same as in the A/A group, as the paternal and maternal B allele effects cancel each other out. In the A/B group there are two subpopulations: the A-pat/B-mat group with phenotypic mean of $\beta_M$ and the A-mat/B-pat group with $\beta_P$ mean. Thus, the two subpopulations combined also have zero mean, but increased variance. doi:10.1371/journal.pgen.1004508.g001

For each target SNP, in each family we searched for trios (or parent-offspring pairs) with heterozygous offspring and determined the parent of origin of the alleles (whenever possible). From each family at most one heterozygous offspring with known parental origin was then collected and grouped according to the parental origin of the alleles. The equality of phenotypic means in the two groups was tested using a Student t-test (“P-value for beta difference column”). The difference between the phenotypic means were meta-analysed using inverse-variance weighting. Table notations: “beta meta” and “P meta”: meta-analysis estimate of beta (coded paternal) - beta (coded maternal) effect size differences and the corresponding P-value, “N meta”: total number of heterozygous offspring with (coded-maternal/other-paternal), (coded-paternal/other-maternal) genotypes, respectively.

doi:10.1371/journal.pgen.1004508.t002
The transformed BMI values resulted in similar results (Table S6), and these adjustments were robust, giving lower priority to the examined SNP. We test for various transformed versions of the phenotype such as log and inverse-normal quantile. If the resulting POE P-values are not significant, we proceed to trio-based confirmation. We recommend the following checks: (a) Exclude SNPs with overdominant effects; (b) For SNPs with low POE P-value, test gene-environment (GxE) interaction (as done in [23]) via modelling phenotypic variance as a function of the genotype dosage (coded in additive, recessive or dominant fashion). If this test is more significant than the POE test, it is probably a GxE that is driving the POE association and also as a side effect we will observe significant difference in the variance between the two homozygous groups. (c) If a SNP with low POE P-value has marginal effect on the trait, repeat the POE test for various transformed versions of the phenotype such as log and inverse-normal quantile. If the resulting POE P-values are not robust, give lower priority to the examined SNP.

For our confirmed SNPs multiple lines of evidence show that the parent-of-origin effects are real, most convincingly clear replication in independent family data of parent-of-origin associations of the hit SNPs with both BMI and gene expression levels. Further, the GWAS discovery associations are very unlikely to be artefacts of the factors discussed above: (i) there is no evidence of overdominant, additive, recessive or dominant effects (the mean BMI values are near identical in the three genotype groups), hence the signals cannot be driven by gene-environment interactions or be an artefact of the scale on which the phenotype is measured; (ii) no SNP within 500 kb has any detectable marginal effect on BMI thus the association cannot be driven by haplotype-specific marginal effects [26]; (iii) the phenotypic variances in the two homozygous groups, are almost identical (rs2471083: $\sigma^2_{TC} = 0.96$, $\sigma^2_{TT} = 1.06$, $\sigma^2_{CT} = 0.98$ and rs3091890: $\sigma^2_{TC} = 0.97$, $\sigma^2_{TT} = 1.05$, $\sigma^2_{CT} = 0.95$); (iv) POE test with log- and inverse-normal quantile transformed BMI values resulted in similar results (Table S6), further reducing the likelihood of an artefact resulting from the scale on which the phenotype is measured [24].

Some of the negative results of the other SNPs carried forward to the replication phase in the family data could be explained by lack of power. The power to replicate POE associations in family-based studies is dependent on the available number of heterozygous individuals (for details see Supplemental Data S1) and thus increases with minor allele frequency (MAF). Therefore, it is unsurprising that the two SNPs which replicated had relatively high MAF (>27%).

Linkage studies have identified four regions exerting POE on BMI (10p12, 12q24, 13q32 [5] and 2q31 [27]). We looked up SNPs in these regions in our genome-wide discovery POE association results. The reported linkage regions showed enrichment for lower than expected POE P-values (see Figure S4 for regional QQ-plots), however, no SNPs survived Bonferroni correction. We also tried to replicate a SNP in exon 5 of DLK1 (rs1802710) because this SNP showed polar overdominance for obesity in children [20], but only a very slight trend ($P = 0.32$) was visible in our study. Previously reported BMI-associated loci [10] show some enrichment for lower POE P-values (Supplemental Data S1, Tables S9, S10 and Figure S5), however these need to be replicated in family studies.

Previous work comparing strength of associations of mother-offspring BMI with father-offspring BMI did not reveal intrauterine influence on obesity in children [28]. A similar conclusion was reached in a systematic review of seven studies [29], while stronger maternal influence was observed in a recent longitudinal study [30]. The difference in conclusions may be due to that fact that the former studies included predominantly older children than the longitudinal study (0–3.5 years). At early age the diet of the offspring may be more similar to that of the mother than the father (e.g. due to breastfeeding), which might have contributed to the higher mother-offspring BMI similarity found by Linabery et al. [30].

In summary, our findings indicate that POEs may play a role in adult obesity. The two identified SNPs have strong parent-of-origin effect on BMI, close to that of the FTO, contributing substantially to the heritability of BMI. Our follow-up experiments demonstrated parent-of-origin specific gene expression modulation, but failed to link methylation activity of these loci to BMI values. Inevitably for newly discovered loci, further studies are warranted to determine how these variations functionally influence obesity in humans. The reliance of our approach on difference in phenotypic variance means that it cannot be extended to binary
SNPs in SLC2A10 and KCNK9 Exhibit Parent-of-Origin Effect on BMI

In the presence of a marginal association a phenotype transformation could alter the genotype group variances and introduce bias into the test [24]. For this reason we analysed untransformed age-, age²-corrected BMI values (normalised to have zero mean and unit variance) separately for men and women. Standard variance tests (such as the F-test) are, however, sensitive to deviations from the Gaussian distribution.

Therefore, we used a robust version of the Brown-Forsythe test. Briefly we first centred the phenotype values (at zero) in each genotype group to avoid inflated variance in the presence of marginal effects in the group of all homozygous individuals. We denote these centred phenotypes by $z$, where

$$z_i = \begin{cases} y_i - \mu_{AA} & \text{if } g_i = AA \\ y_i - \mu_{AB} & \text{if } g_i = AB \\ y_i - \mu_{BB} & \text{if } g_i = BB \end{cases}$$

Here $g_i$ stands for the genotype of individual $i$, and $\mu_j$ represents the mean phenotype value in genotype group $j$, where $j$ can take the values of AA, AB or BB. We then regress the absolute deviations from the mean onto a 0–1 coded genotype group identifier (1 for heterozygous and 0 for homozygous individuals) in order to estimate the POE effect size [31]. This regression result in a slope estimate

$$\hat{b} = \frac{z_{het} - z_{hom}}{n_{AB}}$$

where $z_{het} = \sum_{i \in g = AB} |z_i|/n_{AB}$ and $z_{hom} = \left(\sum_{i \in g = AA} |z_i| + \sum_{i \in g = BB} |z_i|\right)/(n_{AA} + n_{BB})$. The corresponding standard error is

$$SE_{\hat{b}} = \sqrt{\frac{RSS}{n - 1}} \frac{n_{AB}(n_{AA} + n_{BB})}{n},$$

where

$$RSS = \sum_i (z_i - x)^2 - \hat{b}^2 n_{AB}(n_{AA} + n_{BB})/n$$

and $x = \sum_i |z_i|/n$.

Finally, the POE P-value is assigned based on the test statistic $\hat{b}/SE_{\hat{b}} \sim N(0,1)$. The test was extended to imputed genotype probabilities and implemented in the latest version (v0.98) of the Quicktest software (http://www3.unil.ch/wpmu/sgg/quicktest/). The robustness of this test to deviations from normality has been studied in [32] and its power in [31].

SNP selection strategy

We applied our POE test genome-wide to all HapMap imputed markers in a set of cohorts and results were combined across cohorts using fixed-effect inverse-variance weighting meta-analysis. SNPs were selected for replication if they met at least one of the following two criteria: (1) POE P-value $<5 \times 10^{-6}$ or (2) POE P-value $<5 \times 10^{-4}$ and within 500 kb of previously reported imprinted regions according to the Catalogue of Parent of Origin Effects database (http://igc.otago.ac.nz/home.html). At loci which met either criteria, a lead SNP (with the strongest POE association) was identified; other markers within 1 Mb or in LD ($r^2 > 0.1$) were excluded from further investigations. In total 2,673,768 HapMap imputed and genotyped SNPs were analysed,

outcomes. Since there are other phenomena which can give rise to significant POE association, we recommend that top hits from our method are followed up in family studies, where parental origin of alleles can be inferred. In addition, our variance based POE test for GWAS data is naturally much less powerful than actually testing the mean values of the two heterozygous subgroups in trios. However, GWASs of unrelated individuals are several-fold more numerous and typically much larger than studies with a trio design, hence our methodology provides a great advance in parent-of-origin research by providing means to exploit all available GWAS data of unrelated individuals in order to identify parent-of-origin effects on continuous phenotypes.

Materials and Methods

Ethics statement

All participating studies were approved by the respective institutional Ethics Committees. All study participants gave written consent including for genetic studies.

Detecting parent of origin effects

If we denote the alleles of a bi-allelic SNP by “A” (reference) and “B” (alternative) the possible genotypes are A/A, A/B and B/B. Standard GWASs estimate the effect of the alternative allele dosage on the phenotype in question. In this work we are interested in associations in which a phenotype ($y$) is influenced by the alleles of a particular SNP and the effect depends on the parental origin of the A and B alleles. We assume that the phenotype of any individual in the A/A genotype group is modelled by $y_{AA} = \mu_{AA} + \pi$, where $\mu_{AA}$ is the mean and $\pi$ is an individual level error with mean zero and variance $\sigma^2$. If the maternal and paternal effects of the B allele are $\beta_M$ and $\beta_P$, it follows that the phenotype of an individual in the B/B group is $y_{BB} = \mu_{BB} + \beta_M + \beta_P + \epsilon$ and its variance is $\sigma^2$. (Note that as a consequence the maternal and paternal effects of the A allele are $-\beta_P$ and $-\beta_M$.) Here we assume $\sigma^2$ is constant across genotype groups (A/A, A/B and B/B) and $\beta_M$ and $\beta_P$ are fixed effects. The effects of violations of these assumptions are covered in the discussion. The phenotype in the heterozygous group is a 50%-50% mixture of two distributions (Fig 1a):

$$y_{AB} = \mu_{AA} + \pi \beta_M + (1 - \pi) \beta_P + \epsilon,$$

where $\pi$ is a Bernoulli random variable (with parameter $1/2$), taking values $\pi = 1$ if the B allele is inherited from the mother and $\pi = 0$ if inherited from the father. The heterozygous phenotype distribution can be simplified to $y_{AB} = \mu_{AA} + \beta_P + \pi(\beta_M - \beta_P) + \epsilon$ Since $\pi$ and $\epsilon$ are independent random variables, the phenotypic variance of the heterozygous genotype group $\sigma_{AB}^2$ is

$$\text{Var}(y_{AB}) = \text{Var}(\pi)(\beta_M - \beta_P)^2 + \text{Var}(\epsilon) = \frac{1}{4}(\beta_M - \beta_P)^2 + \sigma^2$$

If a parent-of-origin effect is present $\beta_M$ and $\beta_P$ are different, thus $\sigma_{AB}^2$ is larger than the variance observed in the homozygous groups ($\sigma^2$) (Figure 1). Therefore, although in regular GWAS data we cannot identify the two subgroups within A/B genotypes, we can detect POE via increased phenotypic variance in the heterozygous group relative to the homozygous groups.
of which 29,457 were considered as lying in imprinted regions, criterion [2]. Using the procedure of Gao et al. [33] we estimated the effective number of tests considered by each criterion to be \( \sim 1,000,000 \) and 6,100 respectively, justifying the \( \sim 100 \) fold drop in the P-value threshold applied to the second criterion.

Testing in family-based studies

We tested our findings in family-based studies using a simplified parental asymmetry test [34] (PAT). For each target SNP, in each family we searched for trios (or parent-offspring pairs) with heterozygous offspring and determined the parent of origin of the alleles (whenever possible, i.e. at least one homozygous parent). From each family at most one heterozygous offspring with known parental origin was then collected and grouped according to the parental origin of the alleles. Note that although POE is acting in every genotype group, it can only be detected in the heterozygous group.

As at the discovery phase, we used sex-, age- and age\(^2\)-corrected BMI residuals as phenotype. The equality of phenotypic means in the heterozygous group. Let

\[
\hat{\beta}_M - \hat{\beta}_P. 
\]

The difference between paternal and maternal effect alleles can also be derived from GWAS of unrelated individuals. It is easy to see that the test statistic defined as

\[
T = 4\left( \sigma^2_{AB} - \frac{(n_{AA} - 1)\sigma^2_{AA} + (n_{BB} - 1)\sigma^2_{BB}}{n_{AA} + n_{BB}} \right) 
\]

gives an unbiased estimate of \( (\hat{\beta}_M - \hat{\beta}_P)^2 \). Since \( \text{Var}(\sigma^2_{\alpha}) = \frac{2}{n_{\alpha} - 1} \), the variance of \( T \) is \( \approx \frac{1}{n_{AB} + 1} \). Therefore, the absolute difference in paternal and maternal effects \((\hat{\beta}_M - \hat{\beta}_P)\) can be estimated if the phenotypic variances in the three genotype groups are known. However, these estimates will be strongly subject to the winner’s curse [33], thus we used the family studies to derive more reliable estimates of \((\hat{\beta}_M - \hat{\beta}_P)\). To reduce the effect of differences in the distribution of BMI between the family-based studies, we meta-analysed the difference estimates \((\hat{\beta}_M - \hat{\beta}_P)\) from each study in order to obtain a combined estimate of \((\hat{\beta}_M - \hat{\beta}_P)\). The average of the maternal- and paternal effects, \((\hat{\beta}_M + \hat{\beta}_P)/2\), is the association effect size using a simple additive genetic model, which can be most accurately estimated from the largest-to-date meta-analytic study on BMI [10] (including \( \sim 250,000 \) individuals).

Effect size estimation

In order to estimate paternal \( \beta_P \) and maternal \( \beta_M \) effect sizes it is sufficient to know their mean \((\hat{\beta}_M + \hat{\beta}_P)/2\) and their difference \((\hat{\beta}_M - \hat{\beta}_P)\). The difference between paternal and maternal effect alleles can also be derived from GWAS of unrelated individuals. It is easy to see that the test statistic defined as

\[
T = 4\left( \sigma^2_{AB} - \frac{(n_{AA} - 1)\sigma^2_{AA} + (n_{BB} - 1)\sigma^2_{BB}}{n_{AA} + n_{BB}} \right) 
\]

gives an unbiased estimate of \( (\hat{\beta}_M - \hat{\beta}_P)^2 \). Since \( \text{Var}(\sigma^2_{\alpha}) = \frac{2}{n_{\alpha} - 1} \), the variance of \( T \) is \( \approx \frac{1}{n_{AB} + 1} \). Therefore, the absolute difference in paternal and maternal effects \((\hat{\beta}_M - \hat{\beta}_P)\) can be estimated if the phenotypic variances in the three genotype groups are known. However, these estimates will be strongly subject to the winner’s curse [33], thus we used the family studies to derive more reliable estimates of \((\hat{\beta}_M - \hat{\beta}_P)\). To reduce the effect of differences in the distribution of BMI between the family-based studies, we meta-analysed the difference estimates \((\hat{\beta}_M - \hat{\beta}_P)\) from each study in order to obtain a combined estimate of \((\hat{\beta}_M - \hat{\beta}_P)\). The average of the maternal- and paternal effects, \((\hat{\beta}_M + \hat{\beta}_P)/2\), is the association effect size using a simple additive genetic model, which can be most accurately estimated from the largest-to-date meta-analytic study on BMI [10] (including \( \sim 250,000 \) individuals).

Effect of phenotype transformation in case of marginal association

If there is an additive marginal genetic effect influencing the trait certain transformations may inflate the phenotypic variance of the heterozygous group. Let \( \mu \) be the phenotypic mean in the heterozygous group and \( \delta \) the marginal effect of the SNP (on the original scale). Let \( g(t) \) denote an S-shaped transformation function of the form

\[
g(t) = \frac{1}{1 + e^{a(t - \mu)}} \]

that is applied to the trait.

In the following we show that for any \( \delta \) value arbitrarily large phenotypic variance inflation can be achieved in the heterozygous group, compared to the two homozygous groups by an appropriate parameter choice for \( a \). Using a second order Taylor expansion the variance of the transformed phenotype in the heterozygous group can be estimated by

\[
\text{Var}(g(y|G = AB)) \approx g'(\mu)^2 \sigma^2 + \frac{1}{4} g''(\mu) \text{Var}(g(y|G = AB)^2) - 4g'(\mu)\sigma^2 
\]

If we assume the phenotype follows a Gaussian distribution \( (y|G) \) then, \( \text{Var}(g(y|G = AB)^2) \) simplifies to \( 4\sigma^2 + 2\sigma^4 \) and thus

\[
\text{Var}(g(y|G = AB)) \approx g'(\mu)^2 \sigma^2 + \frac{1}{2} g''(\mu)^2 \sigma^4 
\]

Without loss of generality one can assume that \( \sigma^2 = 1 \). The variance in AA genotype group can be estimated similarly and thus

\[
\text{Var}(g(y|G = AB)) - \text{Var}(g(y|G = AA)) 
\]

\[
\approx [g'(\mu)^2 - g'(\mu - \delta)^2] + \frac{1}{2} g''(\mu)^2 - g''(\mu - \delta)^2 
\]

Using the special form of \( g(t) \), the variance difference can be expressed as

\[
\text{Var}(g(y|G = AB)) - \text{Var}(g(y|G = AA)) 
\]

\[
\approx \frac{\alpha^2}{16} \left( 1 - \frac{e^{2\alpha\delta}}{1 + e^{2\alpha\delta}} \right) - \frac{\alpha^2}{2} \left( \frac{e^{\alpha(1 - e^{\alpha\delta})}}{1 + e^{\alpha(1 - e^{\alpha\delta})}} \right) 
\]

\[
= \frac{\alpha^2}{16} \left( 1 - \frac{e^{2\alpha\delta}}{1 + e^{2\alpha\delta}} \right) - \frac{\alpha^2}{2} \left( \frac{e^{\alpha(1 - e^{\alpha\delta})}}{1 + e^{\alpha(1 - e^{\alpha\delta})}} \right) 
\]

\[
= \frac{\alpha^2}{16} \left( 1 - f(a, \delta) \right) 
\]

and since \( g'(\mu - \delta) = g'(\mu + \delta) \) and \( g''(\mu - \delta) = -g''(\mu + \delta) \)

\[
\text{Var}(g(y|G = AB)) - \text{Var}(g(y|G = BB)) 
\]

\[
\approx \text{Var}(g(y|G = AB)) - \text{Var}(g(y|G = AA)). 
\]

It is easy to see that for a fixed \( \delta \)

\[
\lim_{a \to \infty} f(a, \delta) = 0 
\]

As \( a \to \infty \), \( f(a, \delta) \to 0 \) faster than \( a^2 \to \infty \), thus for any effect size \( \delta \) we can find a transformation function \( g \) such that the variance inflation of the heterozygous group exceeds any arbitrary threshold.

Cell lines, nucleic acids isolation, sequencing and qPCR

Lymphoblastoid cell lines were derived from peripheral blood leukocytes of 95 members of 11 CEPH families [36] (#102, #884, #1333, #1340, #1341, #1345, #1346, #1347, #1362, #1408, #13292). They were purchased from the Coriell Cell Repository.
is previously described [37]. DNA was extracted by using the QIAamp DNA Mini kit (QIAGEN), and RNA by using the RNeasy Mini kit (QIAGEN), according to the manufacturer’s instructions. Primer sequences were designed to amplify a 329-bp region on chromosome 8 that spans the rs2471003 polymorphism (forward primer: 5’-ACCA-CAGAAGTCTGACGAG-3’; reverse primer: 5’-GTGAC-CATTGGGACACATGGGA-3’) and a 146-bp region on chromosome 20 that spans the rs3092611 polymorphism (forward primer: 5’-GCCACAGTGGTCTGATAGT-3’; reverse primer: 5’-TAACCTGTCATCTTTGCTCCTGG-3’). PCR amplification was performed in a 25 μl reaction using GoTaq polymerase (Promega). After purification of PCR products (ExoSAP-IT; USB), sequencing reactions were carried out by using 1 μl of each of the 3.2 μM sequencing primers and 0.5 μl of BigDye Terminator v1.1 (Applied Biosystems). Following on-column purification (EdgeBio), sequencing products were run on an ABI-3130 XLS sequencer (Applied Biosystem). To synthesize cDNA, 2 μg of total RNA was retrotranscribed using the Superscript III reverse transcriptase (Invitrogen/Life Technologies) according to the manufacturer’s instructions and a mix of random hexamers and oligo-dT that facilitate the detection of poorly expressed genes. To validate primers for qPCR, we first performed a series of test amplifications using a defined range of primer concentrations (50–200 nM). primers for qPCR, we first performed a series of test amplifications to validate the specificity of the amplification product, which should be highly expressed in these organs. We obtained a standard curve slope of −3.49 for KCNK9 and of −3.37 for SLC2A10, corresponding to 94% and 98% PCR efficiency. For more details see Supplemental Data S1.

Comparing Ct values

The output of the analysis was threshold cycles (Ct), i.e. the number of cycles at which the fluorescent signal of the reaction crosses a pre-determined threshold value. Since standard quantification methods (including normalization by housekeeping genes) introduce a considerable amount of experimental noise for very lowly expressed genes, raw Ct values were used to perform an absolute quantification of KCNK9 and SLC2A10 transcripts. As negative controls, housekeeping genes (HPRT1, GAPDH) were also tested for parent-origin-effect to exclude the possibility that the observed difference in KCNK9 and SLC2A10 expression levels was due to the sample preparation process. Raw Ct values were inverse-normal quantile transformed and a linear mixed model was fitted (using the R function lmer) modelling the technical replicates as random effects and parental origin as a fixed effect.
