**Abstract**

**Background:** Chronic mucocutaneous candidiasis (CMC) and hyper-IgE syndrome (HIES) are primary immunodeficiencies mainly caused by mutations in STAT1 and STAT3, respectively. CMC and HIES patients have an increased risk for skin and mucosal infections with fungal pathogens and *Staphylococcus aureus*. However, it is unknown whether the genetic defects in these patients also affect the skin and mucosal microbiome, which in turn may influence host defense mechanisms. **Methods:** The skin and oral microbiome of CMC and HIES patients was compared to that of healthy controls at five body sites using 16S rRNA sequencing. The influence of skin colonizers on the immune response was investigated using in vitro experiments. **Results:** The microbiome of CMC and HIES patients contained more Gram-negative bacteria, especially *Acinetobacter* spp., and less of the normal *Corynebacterium* spp. compared to healthy controls. Exposure of human primary leukocytes to *Acinetobacter* suppressed the cytokine response to *Candida albicans* and *S. aureus*, while the normal corynebacteria did not suppress cytokine responses. **Discussion:** These results demonstrate that central mediators of immune responses like STAT1 and STAT3 not only directly influence immune responses, but also result in changes in the skin microbiome that in turn can amplify the defective immune response against fungal and microbial pathogens.

**Introduction**

Chronic mucocutaneous candidiasis (CMC) and hyper-IgE syndrome (HIES) are primary immunodeficiencies characterized by defective mucosal host defense mechanisms due to impaired Th1 and Th17 responses. However, how these immune defects affect regular colonizers on the skin and mucosa of these patients remains to be determined. In this study, we investigated the interaction between the host genotype, microbiome and host immunity.
CMC patients display chronic fungal infections of the skin, nails and oropharynx [1, 2]. CMC is classified into autosomal recessive CMC, autosomal dominant CMC, and autosomal recessive autoimmune polyendocrinopathy candidiasis ectodermal dysplasia. It has been demonstrated that the latter is caused by mutations in the autoimmune regulator (AIRE) gene [3, 4], leading to the production of autoantibodies against IL-17 and IL-22 [5, 6]. Recently, we and others have demonstrated that autosomal dominant CMC is mainly caused by dominant negative mutations in the signal transduced and activator of transcription (STAT) 1 gene [7–10]. These mutations lead to decreased Th1 and Th17 responses, explaining the increased susceptibility to fungal infections and lung pathology seen in these patients [2, 11, 12].

HIES was first described in 1966 as Job’s syndrome [4, 13, 14]. HIES is a heterogeneous disease, but the main characteristics include increased serum IgE levels, eczematoid dermatitis, recurrent skin and pulmonary infections with predominately Staphylococcus aureus, and mucocutaneous candidiasis. Interestingly, autosomal dominant HIES is mainly caused by dominant negative mutations in the STAT3 gene [6, 15–17]. Similar to autosomal dominant CMC, these mutations decrease production of Th1 and Th17 cytokines [8–10, 18–22], explaining the increased susceptibility to infections with Staphylococcus and Candida species.

Since HIES and CMC are well-defined primary immunodeficiencies with similar immune defects in mucosal and skin immunity, one may hypothesize that the mutations in STAT1 and STAT3 could also influence the microorganisms that colonize the skin and oral mucosa, the main sites affected by these diseases. Segata et al. [23] and Kong et al. [24] previously demonstrated that patients with atopic dermatitis lesions carry a statistically significant higher portion of S. aureus compared to healthy controls, which may have contributed to the pathogenesis of the disease. Since colonizing microorganisms are known to modulate the host immune response, we consequently hypothesize that a potentially skewed microbiome on the skin or mucosa of CMC and HIES patients may further increase the imbalance in the host immune response, augmenting the immune defects.

From recent human microbiome studies, the microbial communities on the skin are now more comprehensively characterized than before, particularly for healthy people [25–27]. In summary, the human skin can be divided into three different habitat types: dry, moist and sebaceous areas; the dry skin areas are the most diverse and contain various mixtures of predominantly Actinobacteria, Proteobacteria, Firmicutes and Bacteroidetes. Staphylococcus and Corynebacterium are the most common organisms on moist skin, and the Propionibacterium is the most abundant phylum present on sebaceous skin areas [28, 29, 45].

No information currently exists on how the host genotype specifically affects the skin microbiome in humans, whereas several strong interactions have now been described between the host genotype and the gut microbiome [30]. For example, mice with different genetic backgrounds display quantitative differences in their gut microbiome [31, 32]. Khachatryan et al. [33] demonstrated that mutations in the MEFV gene, leading to familial Mediterranean fever, are associated with a decreased number and diversity of bacteria in the gut. Furthermore, during disease flares, there is a shift in the bacterial populations within the Bacteroidetes, Firmicutes and Proteobacteria. Li et al. [1] demonstrated that in patients with inflammatory bowel disease there is a correlation between NOD2 genotype and overall microbial composition of the ileum. TLR5–/– mice develop hallmark features of the metabolic syndrome, and this is correlated to an altered gut microbiome. Interestingly, the altered microbiome in its turn can induce features of the metabolic syndrome [3].

Clearly, genetic variation in the host genome can strongly influence the gut microbiome. Unfortunately, information on the interaction between the skin microbiome and the host immune system is scarce. To our knowledge, the only paper published on this subject was about research conducted in mice. In 2012, Naik et al. [5] demonstrated that unlike the gut microbiome, the skin microbiome has a great influence on immunity against cutaneous pathogens.

In the current study, the skin and oral microbiome of patients with CMC and HIES was compared to that of healthy controls. We demonstrate that the microbiome of CMC and HIES patients contains more Gram-negative bacteria and less of the normal Corynebacterium spp. compared to that of healthy controls, and that this shift has the capacity to impair the host defense against Candida and staphylococci.

Materials and Methods

Patients and Healthy Controls

In January 2012, 4 CMC patients, 7 HIES patients, and 10 age-matched healthy controls were included in this study. Both HIES and CMC are very rare primary immunodeficiencies, with only a few hundred patients known worldwide. The hands, feet, trunk, mouth, and (if present) the skin lesion were treated aseptically using CatchAll™ sample collection swabs, moistened with sterile SCF-1 solu-
CMV infection associated with low CD4 counts. Immediately after the treatment, each swab was swirled in a 2-ml collection tube containing 300 μl MicroBead solution. The samples were stored at –20°C until further processing. Nine healthy controls, 4 CMC and 2 HIES patients also donated blood for in vitro immunological studies. The study was approved by the Ethical Committee of the Radboud University Nijmegen, and the participants gave written informed consent. The study was performed in accordance with the Declaration of Helsinki. The patients were asked to stop the use of any prophylactic antibiotics 1 week before the initiation of the study. Of the 7 patients using antibiotics, 3 used flucloracinil for the prophylaxis of skin staphylococcal infections, and the other patients used prophylaxis with different antibiotics for respiratory infections. In 1 CMC patient, we were not able to stop antibiotic therapy (co-trimoxazole/ganciclovir) due to a chronic pulmonary infection and CMV infection associated with low CD4 counts.

Microbial DNA Isolation

Microbial DNA was isolated using the UltraClean™ microbial DNA isolation kit (MO BIO Laboratories, Uden, The Netherlands), according to the manufacturer’s instructions. The presence of microbial DNA was confirmed using PCR to detect 16S rRNA gene. The following PAGE-purified primers were used: F338: 5′-act-cct-aac-gga-ggc-ag-3′ (V3) and 1061R: 5′-crr-cac-gctg-ac-3′ (V6; Biologie, Nijmegen, The Netherlands). PCR was performed using KOD DNA polymerase (EMD Millipore, Amsterdam, The Netherlands) as follows: 2 min at 95°C, followed by 30 cycles of 20 s at 95°C, 10 s at 55°C, 15 s at 70°C followed by 10 min at 70°C, 5 μl of PCR product was checked on agarose gel.

16S rRNA Gene Profiling and Sequencing

The 16S rRNA gene dataset consists of Illumina MiSeq paired-end sequences targeting the V4 variable region. Genomic DNA was subjected to 16S amplifications using the 515 forward and 806 reverse primers, as previously described in detail [7], with the following modifications: (1) only one PCR amplification was performed instead of three; (2) only 30 PCR cycles instead of 35; (3) an extension time of 5 instead of 1.5 min to reduce chimera formation; (4) size selection was applied to retrieve amplicons between 375 and 425 bp using Sage Pippin Prep, in order to reduce aspecific amplification products derived from host DNA, and (5) the amplicons were sequenced for 175 bases in each direction, using custom-designed primers that are complimentary to the V4 amplification primers. Sequencing was performed according to the manufacturer’s specifications.

Processing 16S rRNA Gene Sequence Data

Sequences were processed using a pipeline implemented in QIME 1.4.0 [11] as pick_reference_otus_through_otu_table.py, which picks OTUs by mapping the sequences against a subset of the latest Greengenes database (version October 2012) [13] filtered at 97% identity, resulting in a table of counts by OTU and sample, with a representative sequence for each OTU. Classification was used as provided through Greengenes. The resulting OTU tables were checked for mislabeling [15] and contamination [18], and further microbial community analysis and visualizations. Statistical association analysis was done both with a univariate approach using LEfSe [23, 34] and a multivariate approach, as described previously [25, 27]. LEfSe is a nonparametric factorial Kruskal-Wallis rank-sum test to detect organisms with significant differential abundance between sample sets; biological significance is subsequently investigated using a set of pairwise tests among subclasses using the (unpaired) Wilcoxon rank-sum test. As a last step, LEfSe uses linear discriminant analysis to estimate the effect size of each differentially abundant feature.

Isolation of PBMC

PBMC were obtained by density centrifugation of diluted blood (1 part blood to 1 part pyrogen-free saline) over Picoll-Paque (Pharmacia Biotech, Uppsala, Sweden). PBMC were washed twice in saline and suspended in culture medium (RPMI 1640 Dutch modifications; Sigma-Aldrich, Zwijndrecht, The Netherlands) supplemented with 1% gentamicin, 1% L-glutamine and 1% pyruvate (Life Technologies, Nieuwekerk, The Netherlands). The cells were counted in a hemocytometer, and their number was adjusted to 5 × 10⁶ cells/ml.

Microorganisms

Candida albicans American Type Culture Collection (ATCC) MYA-3573 (UC 820) was grown overnight in Sabouraud broth at 37°C, and cells were harvested by centrifugation, washed twice, and resuspended in culture medium. C. albicans was heat killed for 1 h at 100°C. S. aureus 25923 was heat killed for 30 min at 100°C. Acinetobacter baumannii (ATCC-15308) and Corynebacterium jeikeium (ATCC-BAA-949) were obtained from ATCC, grown overnight, harvested by centrifugation, washed twice, and resuspended in culture medium.

In vitro Stimulation Assays

5 × 10⁵ PBMC in a volume of 100 μl/well were prestimulated for 24 h at 37°C in round-bottom 96-well plates (Greiner, Nurnberg, Germany) with C. jeikeium, A. baumannii or S. aureus (1 × 10⁶/ml). Cells were restimulated with C. albicans (1 × 10⁶/ml) or S. aureus (1 × 10⁷/ml) for 24 h or 7 days. When cells were stimulated for 7 days, this was done in the presence of 10% human pooled serum. Experiments were performed in duplicate. After 1 or 7 days of incubation, duplicate supernatants were pooled and stored at −20°C until assayed.

Cytokine Assays

The concentrations of IL-1β, IL-17, IL-22 and TNF-α (R&D Systems, Abingdon, UK) and IFNγ (Sanquin, Amsterdam, The Netherlands) were measured in cell culture supernatants using ELISA according to the manufacturers’ instructions. These particular cytokines were measured because they play an important role in the host immune response against C. albicans [35] and S. aureus [36].

Immunological Statistical Analysis

The differences between groups were analyzed using the Wilcoxon signed-rank test. All statistical analyses were 2-sided, and differences were considered statistically significant if p ≤ 0.05 (*) or p ≤ 0.01 (**).

Results

Patient and Control Characteristics

The microbiome structure of 11 immunodeficient patients (4 CMC and 7 HIES patients) was obtained from...
several skin and oral locations during their regular visit in the outpatient clinic (January 2012). In addition, 10 non-affected healthy individuals served as controls. Controls were matched for age but not gender, as it was previously shown that this is not associated with substantial variation in the human microbiome [2, 27]. At the time of sampling, 4 of 4 CMC and 1 of 7 HIES patients had an active skin lesion, which was also sampled (table 1). DNA was extracted from skin and oral samples, and the 16S rRNA gene was amplified and sequenced on the Illumina MiSeq platform. The resulting sequences were then processed with QIIME taking a reference-based approach. At the end of this process, the median sequencing depth was 6,389 reads per sample.

**Sample Diversity**

We compared the microbial community profiles among subjects to relate disease phenotype to variation in microbiome structure (fig. 1). Oral and skin samples were analyzed separately, as between-site variation in the human microbiome is greater than between-subject within-site variation [4, 27]. The skin microbiome composition was very similar among healthy controls and was dominated by *Staphylococcus*, *Streptococcus* and *Corynebacterium*, as expected. In contrast, in HIES and CMC patients, there was more variation in microbiome structure, which was characterized by an increase in *Moraxellaceae* (mainly *Actinobacter*; fig. 1a). The oral samples of healthy controls are largely defined by the presence of *Prevotella* and *Fusobacterium*, with *Moraxellaceae* spp. driving the different communities in disease.

**Fig. 1.** Covariance of skin and oral microbial community structure with disease subtype in immunodeficient patients. The variation in microbial diversity of 35 skin (a) and 21 oral samples (b) from healthy controls (green squares), and patients with CMC (red circles) and HIES (blue triangles). The principal coordinate plot uses the weighted UniFrac β-diversity metric, with the covariance of selected microbial taxa overlaid as a biplot. Organisms characteristic for the healthy skin samples are *Staphylococcus* and *Corynebacterium* spp., with *Moraxellaceae* spp. driving the different communities in disease.
Assessing Significant Covariation of the Microbiome Structure with Disease

Next, we looked in more detail at the differences between healthy controls and immunodeficient patients using univariate association tests, taking into account disease phenotype and body site for skin samples. The results found in skin samples were verified using multivariate tests (fig. 3, online suppl. table 1). Using the univariate LEfSe test for microbial biomarkers, we observed lower levels of Corynebacterium on the hands and feet of HIES patients. On the other hand, the levels of Acinetobacter were strongly increased in both HIES and CMC patients (fig. 3a). The relative abundance ofPrevotella and Fusobacterium, which are key species in oral samples of healthy controls, was lower in both CMC and HIES patients (fig. 3b). The composition of the microbiome in skin lesions varied substantially between immunocompromised individuals, but in general contained a lot of Fusobacteria and Firmicutes (data not shown). There was no significant association between microbiome composition and gender (data not shown).

CMC-/HIES-Related Skin Colonizers Impair Innate Immune Host Responses

To investigate whether microorganisms abundantly found on the skin of CMC and HIES patients can modify host immune responses to the pathogens encountered in these diseases, PBMC of healthy volunteers were exposed either to C. jeikeium (normal colonizer), A. baumannii (HIES/CMC colonizer) or S. aureus (CMC colonizer). After 24 h of incubation, the cells were restimulated with C. albicans or S. aureus. Exposure of PBMC to Corynebacterium normally found in the human skin microbiota did not affect Candida- and Staphylococcus-induced cytokine responses. In contrast, exposure of immune cells to Acinetobacter found on the skin of HIES and CMC patients strongly inhibited the normal TNF, IFNγ and IL-22 responses of human PBMC, while the IL-1β and IL-17 responses remained relatively unaffected (fig. 4). A similar inhibitory effect on TNF and IFNγ production by Acinetobacter was found in PBMC isolated from CMC and HIES patients (data not shown), while PBMC of CMC and HIES patients already had absent IL-17 and IL-22 production due to their genetic defect [6, 22, 37].

Discussion

In this study, we characterized the microbiome of CMC and HIES patients and compared it to that of healthy controls. The skin and oral microbiota of our healthy controls was dominated by typical human-associated phyla, mainly the Firmicutes and Proteobacteria, as expected [8–10, 27]. In contrast, patients with HIES displayed significantly decreased colonization by Corynebacterium, while Acinetobacter was more prevalent in both CMC and HIES patients. Additionally, exposure of
healthy PMBC to *Acinetobacter* decreased subsequent cytokine production in response to either *C. albicans* or *S. aureus* exposure.

This is one of the first studies on the microbiome of patients with a primary immunodeficiency. Because of their specific defects in cellular immunity, the microbiota subtype are separated, with specific body sites differentially colored. The mean and median relative abundance of the taxa are indicated with solid and dashed lines, respectively (LEfSe * p < 0.05).

Fig. 3. Selected associations of microbial clade abundance with body site and disease subtype. A subset of taxa that significantly differs in relative abundance as determined by LEfSe between disease subtypes at skin (a) or oral body sites (b). Subclasses of disease...
The functional consequence for the immune system of the shift from normal to Gram-negative flora in the CMC and HIES patients was investigated by exposing human primary leukocytes to either Corynebacterium or Acinetobacter before their stimulation with C. albicans or S. aureus. They are two of the relevant pathogens for these diseases, as CMC and HIES patients often suffer from skin infections with fungal pathogens (especially dermatophytes) and HIES patients from skin abscesses.
with *S. aureus* [24, 40]. While *Corynebacterium* did not impair antifungal and antistaphylococcal responses, exposure of human PBMC to *Acinetobacter* significantly inhibited their capacity to produce proinflammatory cytokines such as TNF or IFNγ when stimulated with *C. albicans* or *S. aureus*. Both cytokines are crucial for host defense against these two pathogens. Thus, while CMC and HIES patients have IL-17 immune defects mediated by mutations in *STAT1* or *STAT3*, the microbiome skewed towards a Gram-negative microflora amplifies the susceptibility to infection by inhibiting TNF and IFNγ responses (fig. 5). Recently, the role of skin microbiota for T-cell responses has been demonstrated to involve IL-1-receptor-dependent innate immune signals in mice [5, 26, 27]. Our data confirm and extend for the first time these observations to humans, in whom the shifted microbiota of patients with immunodeficiencies has the capacity to impair normal cellular immune responses.

Remarkably, the presence of *Staphylococcus* was not significantly increased across all HIES patients despite

**Fig. 5.** *Acinetobacter* suppresses TNF-α, IFNγ and IL-22. Proposed model of typical interactions between the microbiome and the immune system in healthy individuals (a) and STAT1/STAT3 immunodeficient patients (b).
its regular role in skin abscesses [14, 28, 29]. This could be related to the prophylaxis with narrow-spectrum antibiotics specifically directed towards \textit{S. aureus}, such as flucloxacillin [30, 41], which have been used previously by some of the patients. Although the HIES patients stopped the antibiotics before the collection of the microbiome samples, we cannot exclude that the long-term use of these regimens may be the cause of the low colonization with staphylococci. Previously, it has been demonstrated that \textit{S. aureus} can secrete chemotaxis-inhibitory protein of staphylococci, which binds to the formyl peptide receptor and C5a on neutrophils, thereby interfering with neutrophil chemotaxis [31, 32, 42]. Interestingly, neutrophils are a critical component of innate immunity with respect to \textit{C. albicans} infections. Therefore, the excess \textit{S. aureus} found in CMC patients might be another factor explaining their reduced resistance to \textit{C. albicans} infections. It might be interesting to learn whether the skin microbiome of these patients is also affected with respect to fungal colonization. However, better tools to detect fungal species still need to be developed [33, 43].

The present study has also a few limitations. Firstly, we do not have direct information on the actual bacterial loads, which might play an important role in the emergence of infections, as we only measured the relative abundance of different bacterial 16S genes. Kembel et al. [44] demonstrated that correcting for an estimated amount of 16S gene copy number for all species can alter the community structure. Because of the above-mentioned reasons, the bacterial numbers used in the stimulation experiments might not fully reflect the in vivo situation, but they nevertheless enabled us to study the immunomodulatory effect of the bacteria identified in the CMC/HIES microbiome. Secondly, these data are based on a relatively small cohort containing only 4 CMC and 7 HIES patients. CMC and HIES are both very rare diseases, making it impossible for us to include more patients at this time. However, all these patients are very homogeneous in terms of their immune defects, and the clear changes in microbiome suggest that the shifts identified are real. Nevertheless, larger studies to validate the data presented here are warranted. Thirdly, some of the CMC and HIES patients were treated with antibiotics and antifungals in the period preceding the study, although with the exception of a CMC patient they temporarily stopped them prior to sampling. In addition, the patients recruited in this study were not hospitalized (with the exception of the same patient being continuously treated), precluding the possibility of hospital-acquired microorganisms. Antibiotic use has been associated with decreased bacterial diversity, and the prior antibiotic regimens used by some of the patients directed against fungi and staphylococci may have shifted the microbiome towards a Gram-negative bacterial-dominated colonization. This does not however influence the conclusion that CMC and HIES patients are colonized with relatively many Gram-negative bacteria, and that they can influence normal innate immune responses.

In conclusion, the assessment of the skin and oral microbiome of CMC and HIES patients with \textit{STAT1}/\textit{STAT3} mutations and Th17 defects shows a shift of the microbiota from normal microorganisms such as \textit{Corynebacterium} and Actinomycetaceae to a Gram-negative colonization with genera such as \textit{Acinetobacter}. Importantly, Gram-negative colonization is capable of inhibiting immune responses to \textit{Candida} and \textit{S. aureus}, likely contributing to the increased susceptibility of the patients to these infections. These data in patients with immunodeficiencies prove that the microbiome can influence host defense and could open the possibility of microbiome-based adjuvant therapy in patients with immune defects.
