Atenolol versus Losartan in Children and Young Adults with Marfan’s Syndrome

ABSTRACT

BACKGROUND
Aortic-root dissection is the leading cause of death in Marfan’s syndrome. Studies suggest that with regard to slowing aortic-root enlargement, losartan may be more effective than beta-blockers, the current standard therapy in most centers.

METHODS
We conducted a randomized trial comparing losartan with atenolol in children and young adults with Marfan’s syndrome. The primary outcome was the rate of aortic-root enlargement, expressed as the change in the maximum aortic-root-diameter z score indexed to body-surface area (hereafter, aortic-root z score) over a 3-year period. Secondary outcomes included the rate of change in the absolute diameter of the aortic root; the rate of change in aortic regurgitation; the time to aortic dissection, aortic-root surgery, or death; somatic growth; and the incidence of adverse events.

RESULTS
From January 2007 through February 2011, a total of 21 clinical centers enrolled 608 participants, 6 months to 25 years of age (mean [±SD] age, 11.5±6.5 years in the atenolol group and 11.0±6.2 years in the losartan group), who had an aortic-root z score greater than 3.0. The baseline-adjusted rate of change (±SE) in the aortic-root z score did not differ significantly between the atenolol group and the losartan group (−0.139±0.013 and −0.107±0.013 standard-deviation units per year, respectively; P=0.08). Both slopes were significantly less than zero, indicating a decrease in the degree of aortic-root dilatation relative to body-surface area with either treatment. The 3-year rates of aortic-root surgery, aortic dissection, death, and a composite of these events did not differ significantly between the two treatment groups.

CONCLUSIONS
Among children and young adults with Marfan’s syndrome who were randomly assigned to losartan or atenolol, we found no significant difference in the rate of aortic-root dilatation between the two treatment groups over a 3-year period. (Funded by the National Heart, Lung, and Blood Institute and others; ClinicalTrials.gov number, NCT00429364.)
Marfan's Syndrome Is an Autosomal Dominant Disorder of Connective Tissue Affecting Approximately 1 in 5000 People. Cardiovascular disease, mainly progressive aortic-root dilatation and dissection, is the leading cause of death in Marfan's syndrome. After an open-label, randomized trial comparing propranolol without therapy, published in 1994, showed a reduced rate of aortic enlargement among treated patients, beta-adrenergic receptor antagonists (beta-blockers) became the mainstay of medical management. Current management includes serial cardiac imaging, exercise restriction, administration of beta-blockers, and elective aortic-root replacement. Although early diagnosis and refined medical and surgical treatment have improved survival, patients with Marfan's syndrome continue to have high rates of cardiovascular disease and early death.

Marfan's syndrome is caused by mutations in FBN1, the gene that encodes fibrillin-1, a component of extracellular microfibrils. Fibrillin-1 binds the latent complex of the cytokine transforming growth factor β (TGF-β) and regulates its activation and signaling. Studies in a mouse model of Marfan's syndrome showed that a deficiency of fibrillin-1 was associated with excessive signaling by TGF-β. Excessive TGF-β activation and signaling are currently thought to contribute to the pleiotropic manifestations of Marfan's syndrome, including aortic-root dilatation and dissection.

The angiotensin II type 1–receptor blocker (ARB) losartan has been shown to attenuate TGF-β signaling in some disease states, such as chronic renal failure, presumably by decreasing TGF-β signaling in some disease states, such as angiotensin-converting–enzyme inhibitor, beta-blocker, and activators. The rate of aortic-root growth among mice with Marfan's syndrome treated with losartan was similar to that among wild-type mice and was significantly less than that among untreated littermates with Marfan's syndrome. Although the beta-blocker propranolol also reduced the rate of aortic-root growth among mice with Marfan's syndrome, this effect was much less pronounced than that seen with losartan. Losartan therapy in mice with Marfan's syndrome prevented elastic-fiber fragmentation and therefore preserved aortic-wall architecture. Losartan also decreased the rate of aortic-root dilatation in two small series of children with Marfan's syndrome. The goal of the present trial was to determine whether the rate of aortic-root enlargement during treatment with losartan differs from the rate during treatment with atenolol among patients with Marfan's syndrome and a dilated aortic root.

Methods

Study Design

The study design has been published previously. The trial was designed and performed by the Marfan Trial Subcommittee of the Pediatric Heart Network (see the Supplementary Appendix, available with the full text of this article at NEJM.org). The protocol (available at NEJM.org) was approved by the institutional review board or ethics committee at each study center. The data were collected by center investigators and analyzed at the data coordinating center (New England Research Institutes). The lead statistician (the third author) vouches for the accuracy of the data and analyses, and all the authors vouch for the fidelity of this report to the trial protocol.

The trial was sponsored by the National Heart, Lung, and Blood Institute, with additional financial support provided by the Food and Drug Administration (FDA) Office of Orphan Products Development and the Marfan Foundation. Merck and Teva Canada provided losartan and atenolol, respectively, but these companies had no role in the design or conduct of the trial, data collection or analysis, or the writing of the manuscript or the decision to submit it for publication.

Participants

Inclusion criteria were an age of 6 months to 25 years, a diagnosis of Marfan's syndrome according to the original Ghent criteria (Table S1 in the Supplementary Appendix), and a z score for the maximum aortic-root diameter indexed to body-surface area (hereafter, aortic-root z score) greater than 3.0 (as determined by measurement at the local study site). Exclusion criteria were previous or impending aortic surgery; an aortic-root diameter greater than 5 cm; a history of aortic dissection; a diagnosis of the Loeys–Dietz syndrome or the Shprintzen–Goldberg syndrome; therapeutic rather than prophylactic use of an angiotensin-converting–enzyme inhibitor, beta-blocker, or calcium-channel blocker; prior adverse effects related to treatment with ARB or beta-blocker therapy; or a contraindication to such treatment;
and an inability to complete study procedures. Written informed consent was obtained from each participant or the participant’s parent or guardian.

**STUDY PROCEDURES**

Participants were assigned to atenolol or losartan in a 1:1 ratio with the use of randomly permuted blocks stratified according to age (young adults [defined as male participants 16 to 25 years of age and female participants 15 to 25 years of age] vs. children [male participants younger than 16 years of age and female participants younger than 15 years of age]) and a baseline aortic-root z score of less than 4.5 versus a z score of 4.5 or greater. Dynamic allocation was performed within each center.

Atenolol (at an initial dose of 0.5 mg per kilogram of body weight) was increased on the basis of the hemodynamic response up to a maximum dose of 4.0 mg per kilogram per day (not to exceed a total dose of 250 mg), with a goal of a 20% or greater decrease in the mean heart rate as measured on a 24-hour recording. Losartan (at an initial dose of 0.4 mg per kilogram) was adjusted on the basis of body weight up to a maximum dose of 1.4 mg per kilogram per day (not to exceed a total dose of 100 mg), as recommended by the FDA.

Study personnel supervising the dose adjustments were aware of the treatment assignments. All other persons, including participants, families, and other caregivers, were unaware of the treatment assignments. Losartan was provided by the manufacturer as unmarked white tablets. No unmarked tablets were available for atenolol, which was provided by the manufacturer as white tablets that retained the appearance of the commercially available generic agent, so participants and family members may have determined the study-drug assignment. Echocardiographic core laboratory readers were unaware of both the treatment assignment and the study visit number.

**FOLLOW-UP AND OUTCOMES**

Study visits occurred at baseline and at 6, 12, 24, and 36 months after randomization. Echocardiograms were obtained at each study visit and were interpreted in a core laboratory. Adherence to the treatment regimen was assessed according to the number of tablets or amount of liquid in the medication bottles that were returned.

The primary outcome was the rate of aortic-root enlargement, expressed as the annual change in the aortic-root z score, measured by means of echocardiography as previously described, over the 3-year period after randomization. Secondary outcomes included the rate of change in the absolute diameter of the aortic root; the rate of change in the z score and the absolute diameter of the ascending aorta and the aortic anulus; the rate of change in aortic regurgitation; time to aortic dissection, aortic-root surgery, or death (clinical outcomes); the rate of change in anthropometric outcomes (height, weight, body-mass index, ratio of upper to lower body segment, and ratio of arm span to height); and the incidence of adverse events and participant-reported symptoms.

**STATISTICAL ANALYSIS**

We designed the trial to have, with an alpha level of 0.05, 85% power to detect a treatment difference of 0.194 standard-deviation units (z score units) per year in the aortic-root z score, after adjustment for treatment crossover, an assumed withdrawal rate of up to 20%, and three interim analyses. The resulting target sample was 604 participants.

The primary analysis was based on the intention-to-treat principle. Secondary analyses were performed with the use of multiple imputation for missing data, as well as with the exclusion of 36 participants who were identified after randomization as having a major eligibility violation, and with adjustment for status with respect to a history of an endocrine disorder, because the prevalence of this baseline characteristic was unequal in the two treatment groups. A nominal P value of less than 0.0453 was required for the two-sided analysis of the primary outcome at the completion of the trial because three interim analyses were performed. Adjustments were not made to the significance levels of hypothesis tests for secondary trial outcomes.

Echocardiographic and anthropometric outcomes were modeled with linear regression with the use of mixed effects to account for the longitudinal design, with the use of compound symmetry and unstructured covariance structures, respectively. The baseline-adjusted rates of change in the two treatment groups were compared with the use of a test of the treatment-by-time interaction effect. Linear regression was
used to examine the relationship between heart rate and prescribed dose. The time to clinical events according to treatment group and according to subgroup for all the participants was compared with the use of a log-rank test, with event rates estimated according to the Kaplan–Meier method. The incidence rates of adverse events in the two treatment groups were compared with the use of Poisson regression. Treatment-group comparisons of blood pressure, heart rate, and safety-related laboratory variables were performed with the use of Student’s t-test or a Wilcoxon rank-sum test, and treatment-adherence rates and proportions of participants with each reported drug reaction were compared with the use of Fisher’s exact test.

The prespecified subgroups defined at baseline were young adults versus children, age as a continuous variable, aortic-root z score (<4.5 vs. ≥4.5), and previous use of a beta-blocker (yes vs. no). A differential treatment effect according to prespecified subgroup was identified by an interaction test (subgroup by treatment by time) in the longitudinal regression model for the echocardiographic and anthropometric outcomes and in a Cox proportional-hazards regression model for clinical outcomes.

RESULTS

STUDY PARTICIPANTS
From January 2007 through February 2011, we enrolled 608 participants at 21 clinical centers; 303 participants were randomly assigned to atenolol and 305 to losartan. The numbers of patients who were screened, randomly assigned to a treatment group, and included in the analysis of the primary outcome are shown in Figure 1. Baseline clinical and echocardiographic characteristics were similar between the atenolol group and the losartan group, except for the incidence of endocrine disorders (2% vs. 0%, P=0.007) (Table 1). There was no significant difference in the withdrawal rate (11% in each group) or in the median time from randomization to withdrawal (2.3 years in the atenolol group and 1.9 years in the losartan group, P=0.47).

PRESCRIBED DOSE AND ADHERENCE
The mean dose of atenolol was 2.7±1.1 mg per kilogram per day, and the mean dose of losartan was 1.3±0.2 mg per kilogram per day (Table S2 in the Supplementary Appendix). The mean absolute doses for young adults were 151±75 mg of atenolol per day and 85±14 mg of losartan per day. The proportion of patients who returned at least 60% of medication bottles did not differ significantly between the atenolol group and the losartan group (65% and 64%, respectively; P=0.86). On the basis of the amount of medication in the bottles returned, we estimated that 71% of the participants took at least 80% of the dispensed dose (73% of the participants in the atenolol group and 69% in the losartan group, P=0.30).

BLOOD-PRESSURE AND HEART-RATE EFFECTS
There were no significant differences between the two treatment groups in baseline blood pressure (Table S3 in the Supplementary Appendix). At 3 years, there was a small but significant difference in the mean diastolic pressure (54±8 mm Hg in the atenolol group vs. 56±8 mm Hg in the losartan group, P=0.04) but no significant differences in the systolic pressure or mean blood pressure (Table S3 in the Supplementary Appendix).

As expected, the resting and average 24-hour heart rates were significantly lower at all study visits in the atenolol group than in the losartan group (Table S3 in the Supplementary Appendix). Among children, higher prescribed doses of atenolol were significantly associated with higher resting and average 24-hour heart rates, suggesting a relative lack of heart-rate responsiveness in some participants during the dose-adjustment process (Fig. S1 in the Supplementary Appendix).

AORTIC-GROWTH OUTCOMES
The baseline-adjusted annual rate of change (±SE) in the aortic-root z score did not differ significantly between the atenolol group and the losartan group (−0.139±0.013 and −0.107±0.013 standard-deviation units per year, respectively; P=0.08) (Fig. 2A and Table 2). Both slopes were significantly less than zero, indicating a decrease in the aortic-root z score in the two treatment groups. There was insufficient evidence to declare a differential treatment effect according to any prespecified subgroup analyses (Fig. S2 and S3 in the Supplementary Appendix), including age as a continuous variable (P=0.38 for interaction) and an alternative definition of young adult versus child that was based on attainment of maximal height (P=0.38 for interaction).

A younger age at baseline was associated with...
Figure 1. Screening, Randomization, and Follow-up.
The most common exclusion criterion during the medical-record review (71% of records reviewed) was an aortic-root-diameter z score of less than 3.0. Among the 543 participants who remained in the trial, data for the primary end point at 3 years were available for all but 11, who had unacceptable or missing echocardiograms (5 participants in the atenolol group and 6 in the losartan group). In addition, 3 participants withdrew late from the study (2 participants in the atenolol group because of aortic-root surgery and 1 in the losartan group because of unplanned pregnancy); the echocardiograms obtained at the time of withdrawal for these 3 participants served as the 3 year measurements, yielding a total of 535 participants with data for the primary end point at 3 years (268 participants in the atenolol group and 267 in the losartan group). ARB denotes angiotensin II–receptor blocker.
A greater decrease in the aortic-root z score over time in the atenolol group (P<0.001) and in the losartan group (P=0.002), without a significant difference between the treatment groups (P=0.38 for interaction) (Table S4 in the Supplementary Appendix). The annual change in the aortic-root z score in children and young adults did not vary according to the prescribed dose (P=0.51 for interaction).
interaction in the atenolol group; P=0.78 for interaction in the losartan group) (Table S5 in the Supplementary Appendix).

The average annual rate of change in the absolute diameter of the aortic root was similar in the two treatment groups (Table 2 and Fig. 2B). There were small but significant differences favoring atenolol in the average annual change in the absolute diameter and z score for the aortic annulus, but there were no significant differences in the diameter or z score for the ascending aorta (Table 2). The results of the secondary analyses of the aortic-root z score and data on the anthropometric outcomes are shown in Tables S6, S7, and S8 in the Supplementary Appendix.

**ADVERSE CLINICAL OUTCOMES**
The 3-year rates of aortic-root surgery, aortic dissection, death, and a composite of these events did not differ significantly between the two treatment groups (Fig. 3 and Table 2), nor did the treatment effect depend on subgroup. Additional clinical information regarding participants with these events is provided in the Supplementary Appendix. In an analysis that combined the two treatment groups, the 3-year rate of aortic-root surgery was approximately 2 times as high among young adults as among children (8.5% vs. 3.8%, P=0.03) and approximately 15 times as high among participants with a baseline aortic-root z score of 4.5 or greater as among those with a z score of less than 4.5 (12.2% vs. 0.8%, P<0.001).

**ADVERSE EVENTS AND PARTICIPANT-REPORTED SYMPTOMS**
There was no significant difference between the atenolol group and the losartan group in the overall rate of adverse events (408 events and 365 events, respectively; P=0.10) or serious adverse events (40 events and 50 events, respectively; P=0.31).

The rate of adverse events that were possibly or probably related to the study drug was higher with atenolol than with losartan (204 events vs. 163 events, P=0.03), but the results did not differ significantly when the analysis was restricted to

**DISCUSSION**

In this randomized trial comparing losartan with atenolol in a large cohort of children and young adults with Marfan’s syndrome and a dilated aortic root, we found no significant difference in the rate of aortic-root dilatation, indexed to body-surface area, between the two treatment groups over a 3-year period. The effects of treatment with these agents also did not differ significantly according to prespecified subgroups, including younger versus older participants. We did not find the expected advantage of ARB therapy over beta-blocker therapy. However, we found a small but significant difference in favor of atenolol with regard to the absolute diameter and z score for the aortic annulus. This finding was unexpected, without a clear physiological explanation.

The dose of the beta-blocker used in this study was higher than that used in many other studies. The dose of atenolol was adjusted for a physiological effect, and the rate of change in the aortic-root z score was not related to dose. The dose of losartan reflected FDA recommendations at the time of protocol development and was in a much narrower range than the dose of atenolol. A higher dose of losartan or a different ARB might have shown a greater effect on aortic growth rate. We also found that diastolic blood pressure was slightly but significantly lower in the atenolol group than in the losartan group, an effect that could reduce the aortic growth rate and perhaps counter the effect of ARB-induced suppression of TGF-β signaling in the losartan group.

Although the rate of change in the aortic-root z score did not differ significantly between the two treatment groups, the aortic-root z score decreased significantly over time in each group, particularly in younger versus older participants, which suggests that there may be value in beginning therapy relatively early in the disease course. Without a placebo group, we are not able to evaluate the magnitude of this benefit, although a previous study comparing beta-block-
The graph shows the estimated probability of freedom from aortic dissection, surgery, and death versus years since randomization. The inset shows the same data on an enlarged y axis. The Treatment Group Graph shows that both therapies were effective, with no statistically significant differences in treatment at any time point. The Losartan and Atenolol groups had similar rates of freedom from aortic dissection, surgery, and death. The effect sizes were moderate, with hazard ratios (HRs) of 0.83 (95% confidence interval [CI]: 0.72, 0.96) for Losartan and 0.80 (95% CI: 0.70, 0.92) for Atenolol, respectively. The log-rank test showed a difference of 0.10 between the two groups.

The graph also shows the distribution of participants at risk across years since randomization. The number of participants at risk decreased over time, with a higher number of participants at the start of the study and fewer at the end. The Losartan group had a slightly higher number of participants at risk compared to the Atenolol group, but this difference was not statistically significant.

In conclusion, this trial involving children and young adults with Marfan's syndrome and aortic-root dilatation did not show the expected advantages of losartan over atenolol. The rate of change in the aortic-root z score over the 3-year period did not differ significantly between the atenolol group and the losartan group.
