Abstract

Background: Prevention of rejection after renal transplantation requires treatment with immunosuppressive drugs. Data on their in vivo effects on T- and B-cell phenotype and function are limited.

Methods: In a randomized double-blind placebo-controlled study to prevent renal allograft rejection, patients were treated with tacrolimus, mycophenolate mofetil (MMF), steroids, and a single dose of rituximab or placebo during transplant surgery. In a subset of patients, we analyzed the number and phenotype of peripheral T and B cells by multiparameter flow cytometry before transplantation, and at 3, 6, 12, and 24 months after transplantation.

Results: In patients treated with tacrolimus/MMF/steroids the proportion of central memory CD4⁺ and CD8⁺ T cells was higher at 3 months post-transplant compared to pre-transplant levels. In addition, the ratio between the percentage of central memory CD4⁺ and CD4⁺ regulatory T cells was significantly higher up to 24 months post-transplant compared to pre-transplant levels. Interestingly, treatment with tacrolimus/MMF/steroids resulted in a shift toward a more memory-like B-cell phenotype post-transplant. Addition of a single dose of rituximab resulted in a long-lasting B-cell depletion. At 12 months post-transplant, the small fraction of repopulated B cells consisted of a high percentage of transitional B cells. Rituximab treatment had no effect on the T-cell phenotype and function post-transplant.

Conclusions: Renal transplant recipients treated with tacrolimus/MMF/steroids show an altered memory T and B-cell compartment post-transplant. Additional B-cell depletion by rituximab leads to a relative increase of transitional and memory-like B cells, without affecting T-cell phenotype and function.

Introduction

Life-long use of immunosuppressive drugs is required to prevent rejection after renal transplantation. Nevertheless, the continuous use of immunosuppressive drugs does not preclude the development of chronic rejection, which is a major cause of long-term allograft loss [1]. T cells play an important role in the pathogenesis of rejection via the recognition of alloantigens, resulting in T-cell activation, proliferation, and differentiation into CD8⁺ cytotoxic T cells and CD4⁺ T helper cells [2]. Therefore, the most commonly used immunosuppressive drugs in transplantation are directed against T cells to inhibit these processes [3]. On the other hand, regulatory T cells are able to suppress the immune response and prevent allograft rejection [4]. The balance between memory and regulatory T cells during the course after transplantation can be used to predict renal graft rejection following the reduction of immunosuppressive therapy [5]. Next to T cells, B cells can be involved in graft rejection [6]. The presence of B-cell clusters in renal grafts during acute rejection or the presence of anti-HLA antibodies before transplantation is associated with poorer graft survival [7–9]. Notably, B cells can induce alloimmune responses by acting as professional antigen presenting cells, or by the
production of various (pro-)inflammatory cytokines [10]. Therefore, depletion of B cells in renal transplant recipients might help to prevent allograft rejection. Current immunosuppressive regimens consisting of steroids, a calcineurin-inhibitor, and mycophenolate mofetil (MMF) inhibit B-cell function directly due to inhibition of their proliferation and indirectly via the inhibition of T-cell help. B cells can also be selectively depleted by rituximab (RTX), an anti-CD20 monoclonal antibody. RTX is successfully used in the treatment of B-cell malignancies and autoimmune disorders mediated by T and B cells [11,12]. Although the major target of RTX-based treatment was to reduce the levels of circulating autoantibodies, additional B-cell functions may be affected, such as antigen presentation and cytokine production [13]. Furthermore induction of regulatory T cells (Tregs) was reported after RTX treatment in patients with lupus nephritis [14]. Therefore, next to its effect on B cells, RTX might decrease the chance of rejection after transplantation by affecting the T-cell compartment. Remarkably little is known about the effects of the currently used immunosuppressive strategies on the phenotype and function of T and B cells during the course after renal transplantation. Advancements in multiparameter flow cytometry have made it possible to analyze the effects of immunosuppressive agents on various T- and B-cell subsets in more detail. We had the opportunity to study the effects of standard immunosuppression (tacrolimus, MMF and steroids), with or without the addition of RTX induction therapy on the phenotype and function of T and B cells over time in renal transplant recipients participating in a randomized placebo-controlled trial, studying the efficacy and safety of RTX added to standard immunosuppression. To avoid bias by other immunological events as much as possible, we analyzed only Cytomegalovirus (CMV) seronegative patients who did not meet the primary end point of the clinical trial (biopsy-proven acute rejection), and we excluded patients in whom the immunosuppressive treatment was changed during the follow-up period. Applying these selection criteria, all remaining patients were included: 14 patients in the group treated with tacrolimus, MMF and steroids, and 12 patients in the group additionally treated with RTX (Figure S1). Peripheral blood mononuclear cells (PBMCs) of 4 standard-treated patients and 3 RTX-treated patients were not available at 24 months after transplantation. Table 1 summarizes the characteristics of all patients. The study was approved by the Institutional review board of the Radboudumc Nijmegen. Written informed consent was obtained from all participants.

Cells
Peripheral blood samples were obtained before transplantation, and up to 24 months after transplantation. Whole blood counts were performed and PBMCs were isolated by density gradient centrifugation using Lymphoprep (Lutron, Dieren, The Netherlands). PBMCs were cryopreserved in liquid nitrogen until analysis. For each patient longitudinal flow cytometric analysis was performed for all available samples at the same time.

Flow cytometry
For cell surface staining, the following fluorochrome-conjugated monoclonal antibodies were used: CD3(UCHT1), CD4(13B8.2), CD8(B8.11), CD19(FJ-119), CD24(ALB9), CD38(LS198-4-3), CD45(33), CD45RO(UCHL1), CD127(R34.34) and IgD(IADB6) (all from Beckman-Coulter, Mijdrecht, The Netherlands), CD25(M-A251), CCR4(G1), CCR6(11A9) and CXCXR3(1C6/CX3R3) (BD Biosciences, Erembodegem, Belgium), and BAFF-R(R1C1) (BioLegend, Uithoorn, The Netherlands). Intracellular analysis of IL-2(M-Q1-1H12) (BD Biosciences), IL-4(3D4-8), IL-17(EBIO62CA17), IFNγ(4S.B3) (eBioscience, San Diego, CA, USA), and TNFα(3Mab11) (Dako, Glostrup, Denmark) was performed after fixation and permeabilization, using Fix and Perm reagent (eBioscience). Before intracellular cytokine measurement, the cells were stimulated for 4 hours with PMA (12.5 ng/ml), ionomycin (500 ng/ml) and Brefeldin A (5 μg/ml; Sigma-Aldrich, Zwijndrecht, The Netherlands).

The cell phenotype was analyzed by five-color (FC500) or ten-color flow cytometry (Navios), and data were analyzed using Kaluza software (all from Beckman-Coulter). Isotype controls or unstained cells were used for gate settings. Cell populations >0.1% of the CD45+ lymphocyte population with a threshold of more than 50 cells were considered reliable.

Materials and Methods
Patients
Patients were selected from participants of a clinical trial with RTX in renal transplantation at our hospital (ClinicalTrials.gov, NCT00563331). This study investigated the effectiveness and safety of RTX for prophylaxis of acute rejection after renal transplantation. Patients were randomized between treatment with a single dose of RTX (375 mg/m²) or placebo during transplant surgery. Concomitant immunosuppression consisted of tacrolimus, MMF, and steroids. Patients received 100 mg of prednisolone intravenously during the first 3 days after transplantation and subsequently an oral dose of 15–25 mg/day, tapered to a maintenance dose of 0.1 mg/kg/day. Tacrolimus was started at 0.2 mg/kg/day and the dose was subsequently adjusted to achieve whole-blood trough levels of 15–20 ng/ml during the first 2 weeks, 10–15 ng/ml during weeks 3–6, and 5–10 ng/ml from week 7. MMF was administered at 1000 mg twice daily with a dose reduction to 750 mg twice daily at 2 weeks after transplantation, and discontinued after 6 months.

The current study was carried out as preplanned side study of the clinical trial. To create a homogeneous study population without disturbing immunological events, we selected patients who did not meet the primary end point of the clinical trial (biopsy-proven acute rejection). Moreover, we investigated only Cytomegalovirus (CMV) seronegative patients who received a kidney from a CMV seronegative donor (and thus did not develop CMV infection), and we excluded patients in whom the immunosuppressive treatment was changed during the follow-up period. After

Statistical analysis
Continuous data are expressed as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Wilcoxon signed rank test was used to test differences between each follow-up and pre-transplantation value within the triple immunosuppression-treated group. Statistical testing between RTX- and placebo-treated patients was performed according to distribution and type of data (unpaired T test, Mann-Whitney U, or Fisher’s exact tests). P<0.05 was considered statistically significant. Statistical analysis was performed using GraphPad Prism 5.03 (GraphPad Software Inc., La Jolla, CA, USA).

Results
Phenotype and function of T cells in renal transplant recipients after treatment with tacrolimus, MMF and steroids
CD4+ and CD8+ T cells can be divided into naive, central and effector memory, and highly differentiated memory cells based on
CD27 and CD45RO expression. [15]. The absolute numbers of CD4+ and CD8+ T cells in peripheral blood did not change during the use of triple drug immunosuppression after transplantation (Figure 1A-C). However, the percentages of central memory (TCM; CD27+CD45RO+) CD4+ and CD8+ T cells were significantly higher at 3 months after transplantation compared to before transplantation, while the percentages of effector memory (TEM; CD27−CD45RO−) CD4+ and CD8+ T cells, and regulatory (TREGS; CD25+FoxP3+) CD4+ T cells were significantly decreased. The percentages of naive (TN; CD27+CD45RO−) and highly differentiated memory (TEMRA; CD27−CD45RO−) CD4+ and CD8+ T cells were comparable to pre-transplant levels. Next to the T-cell subset distribution, the ratio between memory and regulatory T cells might be an important determinant of the risk of rejection [16]. Interestingly, the CD4+ TCM/CD4+ TREGS ratio significantly increased from 3 months after transplantation and remained elevated compared to the pre-transplant ratio (Figure 1D). The CD4+ TEM/CD4+ TREGS ratio after transplantation was comparable to pre-transplant levels. Finally, we determined the expression of chemokine receptors associated with T helper (Th) 1 (CXCR3), Th2 (CCR4), and Th17 (CCR6) cells (Figure 1E). The percentage of CXCR3+, Th2 (CCR4), and Th17 (CCR6) cells (Figure 1E). The percentage of CXCR3+, Th2 (CCR4), and Th17 (CCR6) cells (Figure 1E). The percentage of CXCR3+, Th2 (CCR4), and Th17 (CCR6) cells (Figure 1E). The percentage of CXCR3+, Th2 (CCR4), and Th17 (CCR6) cells decreased, while there was a relative increase in CD4+CXCR3− memory and IgD+CD27− B cells. (Figure 3D). The majority of B cells remained positive for B-cell activating factor receptor (BAFF-R) after transplantation. Interestingly, the expression level of BAFF-R increased after transplantation, as documented by an increase in median fluorescence intensity (MFI; Figure 3E–F). Overall, renal transplant recipients treated with tacrolimus, MMF and steroids developed a more memory-like B-cell phenotype.

Under treatment with tacrolimus, MMF and steroids, renal transplant recipients develop a memory-like B-cell phenotype

During immunosuppressive treatment, the absolute B-cell numbers in peripheral blood were comparable to pre-transplant levels up to 24 months after transplantation (Figure 3A). To define whether the composition of the peripheral B-cell compartment was affected, we characterized CD19+ B cells using the Bm1-Bm5 classification [17]. Compared to pre-transplant levels, the percentages of naive Bm2 (IgD−CD38−) and transitional Bm2 (IgD−CD38−) CD19+ cells were lower, and the percentage of late memory Bm5 (IgD−CD38−) cells was higher after transplantation (Figure 3B–C). This shift to a more memory-like phenotype was accompanied by an increase in the percentage of virgin naive Bm1 cells, probably needed for B-cell renewal. Accordingly, using an alternative terminology for B cells, the percentages of transitional CD24+CD38−, mature CD24+CD38−, and naive IgD−CD27− B cells were decreased, while there was a relative increase in CD24+CD38− memory and IgD−CD27− switched memory B cells (Figure S2). At 12 and 24 months after transplantation, there was a higher percentage of CD80+ and CD95+ B cells as compared to before transplantation, supporting the more complete differentiation towards memory cells within the B-cell compartment (Figure 3D). The majority of B cells remained positive for B-cell activating factor receptor (BAFF-R) after transplantation. Interestingly, the expression level of BAFF-R increased after transplantation, as documented by an increase in median fluorescence intensity (MFI; Figure 3E–F). Overall, renal transplant recipients treated with tacrolimus, MMF and steroids developed a more memory-like B-cell phenotype.

A single dose of RTX results in a long lasting B-cell depletion in peripheral blood without affecting the T-cell compartment

The participation of renal transplant recipients in a randomized double-blind placebo-controlled study evaluating the efficacy and safety of RTX when added to triple drug immunosuppression gave us the opportunity to study the effects of additional B-cell depletion on the phenotype and function of T and B cells. RTX treatment resulted in a nearly complete depletion of B cells from the peripheral lymphocyte population up to 12 months after transplantation. Remarkably, the B-cell depletion after a single dose of RTX was long lasting. The absolute numbers of B cells
remained quite low at 24 months after RTX treatment with a median of 9.7 B cells/µl (range 3.0–294.8) compared to a median of 116.4 B cells/µl (range 49.7–379.7) in patients not treated with RTX (Figure 4A–B). Interestingly, at 12 months the percentage of Bm2' (IgD++ CD38++) and Bm3+4 (IgD+ CD38++) cells was significantly higher in RTX-treated patients, while the percentages of Bm1 (IgD+CD38-) and Bm2 (IgD-CD38-) cells were lower in RTX-treated patients. Furthermore, CD4+ T cells can be characterized as regulatory T cells (TREGS, CD25+FOX3+). (B) Shown are the absolute numbers of CD4+ T cells and the percentages of TCM, TEM within the CD4+ T cell population for 14 triple immunosuppression-treated patients before transplantation (t = 0) and at 3, 6, 12 and 24 months after transplantation (n = 10 at 24 m). (C) As described under B, for CD8+ T cells. (D) The ratio between the percentage of CD4+ TCM or TEM and the percentage of TREGS. (E) Longitudinal analysis of the percentages of CXCR3+, CCR4+, and CCR6+ cells within the CD4+ T-cell population of 14 triple immunosuppression-treated patients (n = 10 at 24 m). Results are shown as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Significant differences are indicated compared to pre-transplant levels: *P<0.05, **P<0.01.

doi:10.1371/journal.pone.0112658.g001

Discussion

Despite the extensive clinical experience with currently used immunosuppressive drug regimens, there are limited data
available regarding their effects on the peripheral lymphocyte compartment after kidney transplantation. One study describes the effects of cyclosporine, MMF, steroids, and anti-CD25 monoclonal antibody therapy on T and B cells of mainly CMV seropositive renal transplant recipients at 6, 24, and 60 months after transplantation [18]. This therapy resulted in an increased

Figure 2. *Ex vivo* cytokine production by circulating T cells in renal transplant recipients after treatment with tacrolimus, MMF and steroids. Peripheral blood mononuclear cells (PBMCs) were stimulated for 4 hours in the presence of PMA, ionomycin and Brefeldin A. Shown are the percentages IL-2, IL-4, IL-17, IFNγ or TNFα-producing cells within the CD4+ or CD8+ T-cell population of 14 triple immunosuppression-treated patients before transplantation (t = 0) and at 3, 6, 12, and 24 months after transplantation (n = 10 at 24 m). Results are shown as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Significant differences are indicated compared to pre-transplant levels: *P* < 0.05, **P** < 0.01, ***P*** < 0.001.

(E) Overlay plot of the BAFF-R expression (MFI: median fluorescence intensity) within the CD19+ B-cell population of one patient before transplantation (pre-Tx) and 24 months (24 m) after transplantation under treatment with tacrolimus, MMF and steroids. Gray line shows unstained cells. (F) Summary graph showing the BAFF-R MFI of 14 triple immunosuppression-treated patients before over time (n = 10 at 24 m). Results are shown as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Significant differences are indicated compared to pre-transplant (pre-Tx; t = 0) levels: *P* < 0.05, **P** < 0.01, ***P*** < 0.001.
doi:10.1371/journal.pone.0112658.g003
percentage of CD4⁺CD25⁺ TREGS and CD27⁺ memory B cells in renal transplant recipients compared to healthy donors [18], but the data were not compared with pre-transplant levels. In contrast, we performed a longitudinal analysis of T- and B-cell phenotype and function in CMV seronegative patients who received a kidney from a CMV seronegative donor and did not experience a rejection episode up to 24 months after transplantation. In this homogeneous patient population, not affected by major immunological events, we showed that treatment with the combination of tacrolimus, MMF and steroids had no effects on the total number of T and B cells. Nevertheless, these patients had a higher proportion of central memory CD4⁺ and CD8⁺ T cells at 3 months after transplantation compared to pre-transplant levels. Interestingly, the triple drug immunosuppression resulted in a shift toward a more memory-like phenotype in the B-cell population. Addition of a single dose of RTX resulted not only in a long-lasting B-cell depletion, but also in a higher percentage of transitional B cells upon B-cell recovery at 12 months post-transplant. The additional RTX treatment had no effect on the T-cell phenotype.

Although tacrolimus, MMF, and steroids mainly target T-cell activation, proliferation, and differentiation [3,19], we found that treatment with a combination of tacrolimus, MMF, and steroids, induced only marginal changes in the peripheral T-cell phenotypic. These changes were mainly present within the first 6 months after transplantation, which suggests a role for MMF, as this drug was discontinued at 6 months after transplantation. Ex vivo, the T cells collected from patients treated with triple immunosuppressive

(A) Representative dot plots of CD19⁺ B cells within the CD45⁺ lymphocyte population for a RTX-treated and a triple immunosuppression (IS)-treated patient before transplantation (pre-Tx) and at 3, 12, and 24 months after transplantation. (B) Shown are the absolute numbers of CD19⁺ B cells for RTX (gray, n = 12) and triple IS-treated (white, n = 14) patients before transplantation (t = 0) and up to 24 months after transplantation (n = 10 and n = 9 at t = 24 m, respectively). (C) Pie charts depicting the distribution the different B cells subsets over time using the Bm1-Bm5 classification as depicted in Figure 3B: Bm1 (IgD⁺CD38⁻), Bm2 (IgD⁺CD38⁺), Bm2’ (IgD⁻CD38⁻), Bm3⁺4 (IgD⁻CD38⁺), Early Bm5 (IgD⁻CD38⁻) and Late Bm5 (IgD⁻CD38⁻) cells within the CD19⁺ B-cell population. Data are represented as means of 14 triple IS+RTX-treated and 12 IS-treated patients before transplantation (pre-Tx) and at 3, 12, and 24 months after transplantation (n = 10 and n = 9 at t = 24 m, respectively). (D) Shown are the percentages of CD80⁺, CD95⁺ and BAFF-R⁺ cells within the CD19⁺ B-cell population for RTX- (gray, n = 12) and triple IS-treated (white, n = 14) patients before transplantation (t = 0) and up to 24 months after transplantation. Results are shown as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Significant differences are indicated by asterisks: **P<0.01.
doi:10.1371/journal.pone.0112658.g004
therapy were functional, suggesting that they are only suppressed when the drug is present (during treatment). In addition, we found that the ratio between CD4+ central memory and TREG was increased under triple drug immunosuppressive therapy. Concomitantly, we observed a relative increase of CXCR3+ and CCR6+ CD4+ T cells, chemokine receptors associated with memory or activated Th1 and Th17 cells, respectively. This expression enables them to migrate toward inflammatory sites that express their cognate chemokines [20], such as observed in the graft during rejection [21] and on activated human primary tubular epithelial cells [22].

With respect to B cells, mycophenolic acid, but not tacrolimus, has been shown to inhibit the proliferation and immunoglobulin production in vitro [23]. However, in patients with systemic lupus erythematosus who were treated with MMF, the number and phenotype of B cells were similar to that in controls without immunosuppressive therapy [24]. In our cohort, discontinuation of MMF at 6 months after transplantation resulted in a relative increase of virgin naive Bm1 cells, while naïve Bm2 cells were decreased compared to pre-transplant levels. Transitional Bm2 cells remained low up to 24 months after transplantation, suggesting that their development is mainly suppressed by treatment with tacrolimus and/or steroids. Finally, following the discontinuation of MMF, the percentage of memory B cells became comparable to levels before transplantation. Steroids were also found to have clear effects on B cells; ex vivo immunoglobulin production by PBMC was decreased during treatment with a high dose of prednisolone (60 mg) while a lower dose (30 mg) resulted in an increased production after stimulation [25]. Others have described that steroids have an effect on B-cell activation, while proliferation and activation are less affected [26]. Under combined treatment with tacrolimus, MMF, and steroids, our renal transplant recipients had a more memory-like B-cell phenotype compared to before transplantation. This relative increase of memory B cells was also found in a patient cohort treated with cyclosporine, MMF, steroids, and an anti-CD25 monoclonal antibody [10]. The observed memory-like B-cell phenotype was accompanied by an increased percentage of CD19++ and CD19+ B cells, which may be explained by the preferential expression of these molecules in memory-like B cells [17].

Treatment with RTX provides a highly efficient means for the (temporary) depletion of B cells, with potential suppression of B-cell-associated anti-graft responses. Adding a single dose of RTX to the combination of tacrolimus, MMF, and steroids in our patients indeed resulted in a long lasting B-cell depletion in peripheral blood. A remarkable characteristic of the returning B cells was a decreased expression of the receptor for B-cell activating factor (BAFF), an essential growth factor for B cells [27]. The decreased percentage of BAFF-R++ B cells after RTX treatment, which was also found in patients with rheumatoid arthritis [29] may be due to a relative increase of memory-like B cells, which have lower or no BAFF-R expression [27]. In addition, treatment with B-cell depleting agents has previously been shown to elevate BAFF levels [29–31], and increased BAFF levels in turn were inversely correlated with BAFF-R expression [28]. Another interesting observation was an increase in the percentage of transitional B cells at 12 months after treatment with RTX compared to triple immunosuppression therapy alone. Interestingly, BAFF-R deficiency in patients with common variable immunodeficiency (CVID) was associated with B-cell lymphopenia and a relative increase in the number of transitional B cells [33]. Taken together, an increase in BAFF level, reduced BAFF-R expression, and an increase in the proportion of transitional B cells appear to be interrelated phenomena which are associated with RTX treatment.

Upon activation, B cells are able to proliferate, produce various cytokines and process antigen for presentation to T cells [34–36]. Previously, we showed that in vitro RTX treatment can affect B-cell phenotype and function, resulting in an altered outcome of B-T-cell interaction upon stimulation [37]. However, in contrast, we did not observe any changes in the T-cell compartment in our patients treated with RTX. In another ex vivo study, we neither were able to show that RTX influenced the production of IL-17 and other monocyte- and T-cell-derived cytokines by PBMCs [38]. It should be noted however that we only analyzed peripheral blood T cells. From a previous study in renal transplant patients, we know that a single dose of RTX leads to a nearly complete B-cell depletion in peripheral blood, but not in secondary lymphoid organs, and that these remaining B cells have different functional capacities [39]. From our current data, it seems that this population of mostly memory type B cells residing in lymphoid organs does not noticeably affect the peripheral blood T-cell compartment as compared to transplant recipients on triple immunosuppression without RTX. Interestingly, several studies on patients with autoimmune disease revealed that the T-cell compartment was affected upon RTX treatment [12,40,41]. However, in most of these patients the cumulative dose of RTX was higher than in our patients, who received only a single, relatively low dose [40].

In summary, we have demonstrated that treatment of renal transplant recipients with tacrolimus, MMF and steroids leads to alterations in the T- and B-cell compartments. This detailed longitudinal analysis provides more insight into the immune status of renal transplant recipients with stable graft function and may be used as a reference in the monitoring of renal transplant patients.

(A) Shown are the percentages of transitional CD24++CD38+, naïve IgD−CD27− and switched memory IgD+CD27+ B cells within the CD19+ B-cell population for RTX- (gray, n = 14) and triple IS-treated (white, n = 12) patients before transplantation (t = 0) and up to 24 months after transplantation (n = 10 and n = 9 at t = 24 m, respectively). (B) The percentage of regulatory T cells (TREGs: CD25+CD122+, central memory (TCM; CD27+CD45RO−), effector memory (TEM; CD27−CD45RO+), CXCR3+ and CCR6+ within the CD4+ T-cell population in
RTX- (gray, n = 12) and triple IS-treated (white, n = 14) patients before transplantation (t = 0) and up to 24 months after transplantation (n = 10 and n = 9 at t = 24 m, respectively). (C) Peripheral blood mononuclear cells (PBMCs) were stimulated for 4 hours in the presence of PMA, ionomycin and Beclin A. Shown are the percentages IL-2, IL-4, IL-17, IFN+ or TNF- producing cells within the CD4+ T-cell population in RTX- (gray, n = 12) and triple IS-treated (white, n = 14) patients before transplantation (t = 0) and up to 24 months after transplantation (n = 10 and n = 9 at t = 24 m, respectively). Results are shown as box plots displaying the median, 25th and 75th percentiles as the box, and the 5th and 95th percentiles as whiskers. Significant differences are indicated by asterisks: **P < 0.01.

**Author Contributions**

Conceived and designed the experiments: EGK HJPMK MCB IJ LBH. Performed the experiments: EGK. Analyzed the data: EGK HJPMK MCB IJ LBH. Contributed to the writing of the manuscript: EGK HJPMK MCB IJ LBH. Provided patient data: MWvBH LBH.
