Abstract
In the recent years, the Metis prover based on ordered paramodula-
tion and model elimination has replaced the earlier built-in methods for
general-purpose proof automation in HOL 4 and Isabelle/HOL. In the
annual CASC competition, the leanCoP system based on
connection tableaux has however performed better than Metis. In
this paper we show how the leanCoP’s core algorithm can be im-
plemented inside HOL Light. leanCoP’s flagship feature, namely
its minimalistic core, results in a very simple proof system. This
plays a crucial role in extending the MESON proof reconstruction
mechanism to connection tableaux proofs, providing an implementa-
tion of leanCoP that certifies its proofs. We discuss the differ-
ces between our direct implementation using an explicit Pro-
log stack, to the continuation passing implementation of
general purpose TPTP prover. We compare its performance agains t
Metis present in
HOL Light

1. Introduction and Related Work
The leanCoP [19] automated theorem prover (ATP) has an unusu-
ally good ratio of performance to its implementation size. While its
core algorithm fits on some twenty lines of Prolog, starting with
CASC-21 [27] it has regularly beaten Otter [17] and Metis [7]
in the FOF division of the CASC ATP competitions. In 2014, leanCoP solved 158 FOF problems in CASC-J7 [8] while Prover9 solved 95 problems. On the large-theory (chaoty) division of the
MPTP Challenge benchmark [3], leanCoP’s goal-directed calculus
beats also SPASS 2.2 [31], and its further AI-style strengthening
by integrating into leanCoP’s simple core learning-based guidance
trained on such larger ITP corpora is an interesting possibility [34].

Compact ATP calculi such as leanTAP [5] and MESON [16]
have been used for some time in Isabelle [20, 21] and HOLs [4]
as general first-order automation tactics for discharging goals that are
already simple enough. With the arrival of large-theory “hammer”
linkups [2, 13, 25] between ITPS, state-of-the-art ATPs such as
Vampire [12] and E [24], and premise selection methods [14],
such tactics also became used as a relatively cheap method for
reconstructing the (minimized) proofs found by the stronger ATPs.
In particular, Hurd’s Metis has been adopted as the main proof
reconstruction tool used by Isabelle’s Sledgehammer linkup [3]
while Harrison’s version of MESON could reconstruct in 1
second about 80% of the minimized proofs found by E in the first
experiments with the HOL Light hammer linkup [4].

Since HOL Light already contains a lot of the necessary in-
frastucture for Prolog-style proof search and its reconstruction,
inTEGRATING leanCoP INTO HOL Light in a similar way as MESON
should not be too costly, while it could lead to interesting s trength-
ening of HOL Light’s first-order automation and proof reconstruc-
tion methods. In this paper we describe how this was done, resulting
in an OCaml implementation of leanCoP and a general leanCoP
first-order tactic in HOL Light. We compare their performance with
MESON, Metis and the Prolog version of leanCoP in several sce-
narios, showing quite significant improvements over MESON and
Metis.

2. leanCoP and Its Calculus
leanCoP is an automated theorem prover for classical first-order
logic based on a compact Prolog implementation of the clausal
connection (tableaux) calculus [4, 12] with several simple strategies
that significantly reduce the search space on many problems. In
contrast to saturation-based calculi used in most of the state-
of-the-art ATPs (E, Vampire, etc.), connection calculus implement
goal-oriented proof search. Their main inference step connects a
literal on the current path to a new literal with the same predicate
symbol but different polarity. The formal definition (derived from
Otten [18]) of the particular connection calculus relevant in lean-
CoP is as follows:

DEFINITION 1. [Connection calculus] The axiom and rules of the
connection calculus are given in Figure 1. The words of the cal-
culus are tuples “C, M, Path” where the clause C is the open
subgoal, M is a set of clauses in disjunctive normal form (DNF)
transformed from axioms and conjecture with added nullary predi-
cates to all positive clause and the active path Path is a subset
of a path through M. In the rules of the calculus C, C’ and C” are
clauses, σ is a term substitution, and L1, L2 is a connection with

http://www.cs.miami.edu/~tptp/CASC/J7/WWWFiles/DivisionSummary1.html
http://www.cs.miami.edu/~tptp/MPTPChallenge/

[Copyright notice will appear here once ‘preprint’ option is removed.]

1 We suppose that ∈ is a new predicate that does not occur anywhere in
2 axioms and conjecture
3 Thus by default all positive clauses are used as possible start clauses.
\[\sigma(L_1) = \overline{\sigma(L_2)}.\] The rules of the calculus are applied in an analytic (i.e. bottom-up) way. The term substitution \(\sigma\) is applied to the whole derivation.

The connection calculus is correct and complete \([13]\) in the following sense: A first-order formula \(M\) in clausal form is valid iff there is a connection proof for \(\neg M, \{\}\), i.e. a derivation for \(\neg M, \{\}\) in the connection calculus so that all leaves are axioms. The Prolog predicate `prove/5` implements the axiom, the reduction and the extension rule of the basic connection calculus in `leanCoP`:

```prolog
prove(Lit|Cla,Path,PathLim,Lem,Set) :-
prove(Cla|Lit,Path,PathLim,Lem,Set).
prove(Lit,Path,PathLim,Lem,Set) :-
member(NegLit,Path),
unify_with_occurs_check(NegLit,NegL).
```

The tuple \(C, M, Path\) in connection calculus is here represented as follows:

- \(C\) representing the open subgoal is a Prolog list \(Cla\);
- the active path \(Path\) is a Prolog list \(Path\);
- \(M\) is written into Prolog’s database before the actual proof search starts in a such way that for every clause \(C \in M\) and for every literal \(C \in M\) the fact \(lit(Indexing\_L,L,CnGrnd)\) is stored, where \(Cl=C\setminus\{L\}\) and \(CnGrnd\) is \(g\) if \(C\) is ground, otherwise \(CnGrnd\) is \(n\). \(Indexing\_L\) is same as \(L\) modulo all its variables which are fresh (there is no twice or more occurrences in \(Indexing\_L\) everywhere in \(Indexing\_L\) and it is used for fast finding the right fact in database without affecting the logically correct \(L\) by standard Prolog unification without occurs check.
- Atoms are represented by Prolog atoms, negation by \(\neg\).
- The substitution \(\sigma\) is stored implicitly by Prolog.

\(PathLim\) is the current limit used for iterative deepening, \(Lem\) is the list of usable (previously derived) lemmas, \(Set\) is a list of options, and \(Proof\) is the resulting proof. This predicate succeeds (using iterative deepening) iff there is a connection proof for the tuple represented by \(Cla\), the DNF representation of the problem stored in Prolog’s database using the \(lit\) predicate, and a \(Path\) with \([\text{Path}|\text{Path}\) where \(PathLim\) is the maximum size of the active \(Path\). The predicate works as follows:

Line 18 implements the axiom, line 4 calculates the complement of the first literal \(Lit\) in \(Cla\), which is used as the principal literal for the next reduction or extension step. The reduction rule is implemented in lines 7, 8 and 17. At line 7 and 8 it is checked whether the active path \(Path\) contains a literal \(NegLit\) that unifies with the complement \(NegLit\) of the principal literal \(Lit\). In this case the alternative lines after the semicolon are skipped and the proof search for the premise of the reduction rule is invoked in line 17. The extension rule is implemented in lines 10, 11, 14 and 17. Lines 10 and 11 are used to find a clause that contains the complement \(NegLit\) of the principal literal \(Lit\). \(Cla\) is the remaining set of literals of the selected clause and the new open subgoal of the left premise. The proof search for the left premise of the extension rule, in which the active path \(Path\) is extended by the principal literal \(Lit\), is invoked in line 14, and if successful, we again continue on line 17.

Compared to standard tableaux or sequent calculi, connection calculi are not confluent\(^5\). To achieve completeness, an extensive use of backtracking is required. `leanCoP` uses two simple incomplete strategies (namely options `scut` and `cut`) for restricting backtracking that significantly reduces the search space \([18]\) without affecting the ability to find proofs in most tested cases (see Section 4).

Another major problem in connection calculi is the integration of equality. The paramodulation method that is widely used in saturation-based ATPs is not complete for goal-oriented approach of connection calculi. Therefore equality in `leanCoP` and similar ATPs is usually managed by adding the axioms of equality (reflexivity, symmetry, transitivity and substitutivity).

To obtain the clausal form, `leanCoP` uses its own implementation of classifier introducing definitions (the `def` option), which seems to perform better with the `leanCoP`’s core prover than other standard classifiers (TPTP2X using the option `¬clause` and `tptp`, FLOTTER and E) or direct transformation into clausal form using `nodef` option in `leanCoP` \([18]\). In the following subsections, we summarize several further methods used by `leanCoP` that improve its performance.

### 2.1 Iterative Deepening

Prolog uses a simple incomplete depth-first search strategy to explore the search space. This kind of incompleteness would result in a calculus that hardly proves any formula. In order to obtain a complete proof search in the connection calculus, iterative deepening on the proof depth, i.e. the size of the active path, is performed. It is achieved by inserting the following lines into the code:

```prolog
(12) ( Grnd\_eq -> true ; length(P, K), \%Path\_lim = PathLim -> true ;
(13) \+ pathlim -> assert(pathlim, fail),
```

and the whole prover runs in the following iterative sense starting from `PathLim=1`:

```prolog
prove(PathLim,Set) :-
retract(pathlim) ->
PathLim \+ PathLim,1,
prove(PathLim,Set).
```

When the extension rule is applied and the new clause is not ground, i.e. it does not contain any variable, it is checked whether the size \(K\) of the active path exceeds the current path limit `PathLim`.

\(^5\) Bad choice of connection might end up in dead end
(line 12). In this case the dynamic predicate pathlim/0 is written into the Prolog's database (line 13) indicating the need to increase the path limit if the proof search with the current path limit fails. If the proof search fails and the predicate pathlim can be found in the database, then PathLim is increased by one and the proof search starts again.

2.2 Regularity Condition Optimization

**Definition 2.** A connection proof is regular iff no literal occurs more than once in the active path.

Since the active path corresponds to the set of literals in a branch in the connection tableau representation, a connection tableau proof is regular if in the current branch no literal occurs more than once. The regularity condition is integrated into the connection calculus in Figure 1 by imposing the following restriction on the reduction and extension rule: ∀L′ ∈ C ∪ {L1} : σ(L′) ∉ σ(Path).

**Lemma 2.1.** A formula M in clausal form described above is valid iff there is a regular connection proof for ~¬-goal, M, {}.

Regularity is correct, since it only imposes a restriction on the applicability of the reduction and extension rules. The completeness proof can be found in [13, 19].

The Prolog predicate \(+ Goal\) succeeds only if \(Goal\) cannot be proven. In line 3 the corresponding Goal succeeds if the open subgoal \([Lit|Cla]\) contains a literal \ LitC that is syntactically identical (built-in predicate \==/2 in Prolog) with a literal \ LitP in the active path \ Path. The built-in predicate \member/2 is used to enumerate all elements of a list.

2.3 Lemmata optimization

The set of lemmata is represented by the list \Lem. The lemma rule is implemented by inserting the following lines:

\begin{verbatim}
(5) \{ member(LitL,Lem), Lit==LitL \} ;
(6) ;
\end{verbatim}

In order to apply the lemma rule, the substitution \σ is not modified, i.e. the lemma rule is only applied if the list of lemmata \Lem contains a literal \ LitL that is syntactically identical with the literal \ Lit. Furthermore, the literal \ Lit is added to the list \Lem of lemmata in the (left) premise of the reduction and extension rule by adapting the following line:

\begin{verbatim}
(15) prove(Cla,Path,PathLim,[Lit|Lem],Set).
\end{verbatim}

In the resulting implementation, the lemma rule is applied before the reduction and extension rules.

2.4 Restricted backtracking

In Prolog the cut (!) is used to cut off alternative solutions when Prolog tries to prove a goal. The Prolog cut is a built-in predicate, which succeeds immediately when first encountered as a goal. Any attempt to re-satisfy the cut fails for the parent goal, i.e. other alternative choices are discarded that have been made from the point when the parent goal was invoked. Consequently, restricted backtracking is achieved by inserting a Prolog cut after the lemma, reduction, or extension rule is applied. It is implemented by inserting the following line into the code:

\begin{verbatim}
(16) \{ member(cut,Set) -> ! ; true \},
\end{verbatim}

Restricted backtracking is switched on if the list \Set contains the option \cut. The restricted start step is used if the list \Set includes the option \scut. In this case only the first matching clause to starting \¬\Lit literal is used. Restricted backtracking and restricted start step lead to an incomplete proof search. In order to regain completeness, these strategies can be switched off when the search reaches a certain path limit. If the list \Set contains the option \comp(Limit), where \Limit is a natural number, the proof search is stopped and started again without using incomplete search strategies.

3. OCaml Implementation

In this section, we first discuss our implementation\[6\] of leanCoP in OCaml and its integration in HOL Light: the transformation of the higher-order goal to first order and the proof reconstruction. After that we compare our implementation to Harrison’s implementation of MESON.

3.1 leanCoP in OCaml

Otten’s implementation of leanCoP uses the Prolog search, backtracking, and indexing mechanisms to implement the connection tableau proof search. This is a variation of the general idea of using the “Prolog technology theorem prover” (PTTP) proposed by Stickel [25], in which connection tableaux takes a number of advantages from its similarity to Prolog.

In order to implement an equivalent program in a functional programming language, one needs to use either an explicit stack for keeping track of the current proof state (including the trail of variable bindings), or the continuation passing style. We choose to do the former, namely we add an explicit \texttt{todo} (stack), \texttt{subst} (trail) and \texttt{off} (offset in the trail) arguments to the main \texttt{prove} function. The stack keeps a list of tuples that are given as arguments to the recursive invocations of \texttt{prove}, whose full OCaml declaration (taking the open subgoal as its last argument) then looks as follows:

\begin{verbatim}
let rec lprove off subst path limit lemmas todo = function
  | [] -> begin ... end
  | ((lit1 :: rest_clause) as clause) -> ...
\end{verbatim}

The function performs the proof search to the given depth, and if a proof has not been found, it returns the unit. It takes special attention to traverse the tree in the same order as the Prolog version. In particular, when the global option "cut" (restricting backtracking) is off, it performs all the backtrackings explicitly, whereas if "cut" is on, the parts of backtracking avoided in Prolog are also omitted. When a proof is found, the exception 'Solved' is raised: no further search is performed and the function exits with this exception.

The OCaml version and the Prolog version (simplified and with symbols renamed for clarity of comparison) are displayed together in Fig 2. The algorithm proceeds as follows:

1. If nonempty, decompose the current open subgoal into the first literal \lit and the rest \cla.
2. Check for intersection between the current open subgoal and \path.
3. Compute the negation of \lit.

\[6\] Available online at \url{http://cl-informatik.uibk.ac.at/users/cek/cpp15}

3 2014/10/22
1 let rec prove path lim lem set = function (lit :: cla) ->
2 if not ((exists (fun litp -> exists (substeq litp) path))
3 (lit :: cla)) then ( prove path lim lem set )
4 else if not (fold_left (fun sf plit -> sf then true else try
5 (unify_lit nit plit) ; prove path (lit :: lem) ;
6 cut ; with Unify -> sf) false path) then ( prove path lim lem set )
7 else if lit is among the lemmas lem, so try to prove cla.
8 If cut is set, no other options are tried.
9 For each literal on the path, if neglit unifies with it, try to
10 prove cla. If the unification succeeded and cut is set, no other
11 options are tried.
12 For each clause in the matrix, try to find a literal that unifi-
13 es with neglit, and then try to prove the rest of the newly
14 created subgoal and the rest of the current open subgoal. If the
15 unification and the first proof succeeded and cut is set, no other
16 options are tried.
17 When the current open subgoal is empty, the subproof is fin-
18 ished (the axiom rule).

In Otten’s implementation, the behaviour of the program with
19 cut set is enabled by the use of the Prolog cut (!). Implementing
20 it in OCaml amounts to a different mechanism in each of the three
21 cases. In point 4 in the enumeration above, given that a single
22 lemma has been found, there is no need to check for other lemmas.
23 Therefore a simple List.exists call is sufficient to emulate
24 this behaviour in OCaml. No backtracking over other possible
25 occurrences of the lemma is needed here, and it is not necessary
26 to add in this case the literal again into the list of lemmas as is done
27 in the Prolog code (last-but-one line).

In point 5, multiple literals on the path may unify with differ-
28 ent substitutions. We therefore use a list fold mechanism which
29 changes the value whenever the unification is successful and cut
30 is set. In point 6, we need to change our behaviour in between two
31 successive calls to prove. As the first call takes the arguments to
32 the second call on the stack, we additionally add a cut marker on
33 the stack and handle an exception that can be raised by the call on
34 the stack.

Whenever the clause becomes empty, all the tuples in the stack
35 list need to be processed. For each tuple, the first component is
36 the cut marker: if it is set, the Cut exception is raised with a
37 depth level. The exception is handled only at the appropriate level.

This directly corresponds to the semantics of the cut operator in
38 Prolog [26].

What remains to be implemented is efficient equality checking and
39 unification. Since we want to integrate our mechanism in HOL
40 Light, we reuse the first order logic representation used in the
41 implementation of HOL Light’s MESON procedure: the substitu-
42 tions are implemented as association lists, and applications of substi-
43 tutions are delayed until an actual equality check or a unifica-
44 tion step.

3.2 leanCoP in HOL Light

In order to enable the OCaml version of leanCoP as a proof tactic
45 and procedure in HOL Light, we first need to transform a HOL
46 goal to a leanCoP problem and when a proof has been found we
47 reapply the proof in higher-order logic. In order to transform a
48 problem in higher-order logic to first-order logic without equality,
49 we mostly reuse the steps of the transformation already used by
50 MESON, additionally ensuring that the conjecture is separated
51 from the axioms to preserve leanCoP’s goal-directed approach.

The transformation starts by assuming the duplicated copies of
52 polymorphic theorems to match the existing assumptions. Next the
53 goal axioms → conjecture is transformed to (axioms ∧ δ) →
54 (conjecture ∧ δ) with the help of a special symbol, which we
55 define in HOL as: δ = ⊤. Since the conjecture is refuted and the
56 problem is converted to CNF, the only positive occurrence of δ is
57 present in a singleton clause, and the negative occurrences of δ are
58 present in every clause originating from the conjecture. The CNF
59 clauses directly correspond to the DNF used by the Prolog version
60 of leanCoP. Since no steps distinguish between the positivity of
61 literals, the two can be used interchangeably in the proof procedure.

We start the FOL algorithm by trying to prove ¬δ.

Since the final leanCoP proof may include references to lemm-
62 as, the reconstruction cannot be performed the same way as it is
done in MESON. There, a tree structure is used for finished proofs.
Each subgoal either closes the branch (the literal is a negation of a
literally already present on the path) or is a branch extension with

Figure 2. The simplified OCaml and Prolog code side by side. The explicit argu-
63 ment and the computation of the resulting proof have been omitted for clarity, and some symbols were renamed to better correspond to each other. White-space and order of clauses has been modified to exemplify corresponding parts of the two implementations. Function substeq checks equality under the current context of variable bindings. Note that the last-but-one line in the Prolog code was merged into each of the three cases in the OCaml code. See the function lprove in file leancop.ml on our web page for the actual (non-simplified) OCaml code.
a (possibly empty) list of subgoals. In leanCoP, each subgoal can refer to previous subgoals, so the order of the subgoals becomes important. We therefore flatten the tree to a list, which needs to be traversed in a linear order to reconstruct the proof.

We define a type of proof steps, one for each proof step in the calculus. Each application of a lemma step or path step constructs a proof step with an appropriate first-order term. For an application of a tableaux extension step we use Harrison’s contrapositive mechanism: we store the reference to the actual transformed HOL theorem whose conclusion is a disjunction together with the number of the disjunct that got resolved.

```ocaml
let rec mesexpand rules ancestors g cont (env,n,k) = 
  if n < 0 then failwith "too_deep" else
  try tryfind (fun a -> cont (unify_literals env (g,negate a),n,k))
    ancestors
  with Failure -> tryfind (fun rule ->
    let (asm,c), k = renamerule k rule in
    itlist (mesexpand rules (g:ancestors)) asm cont
    {unify_literals env (g,c),n - length asm, k }) rules;;
```

A list of such proof steps together with a final substitution and an initially empty list of already proved lemmas are the complete input to the proof reconstruction procedure. The reconstruction procedure always looks at the first step on the list. First, a HOL term is constructed from the FOL term with the final substitution applied. This step is straightforward, as it amounts to reversing the mapping of variables and constants applied to transform the HOL CNF to FOL CNF, with new names invented for new variables. Next, we analyze the kind of the step. If the step is a path step, the theorem \( tm \vdash tm \) is returned, using the HOL ASSUME proof rule. If the step is a lemma step, the theorem whose conclusion is equal to \( tm \) is found on the list of lemmas and returned. Finally, if the proof step is an extension step, we first find the disjuncts of the HOL theorem in the proof step apart from the one that got matched. We then fold over this list, at every step calling the reconstruction function recursively with the remaining proof steps and the list of lemmas extended by each of the calls. The result of the fold is the list of theorems \( \{ \vdash tm_1, \vdash tm_2, ... , \vdash tm_n \} \) which gets matched with the contrapositive theorem \( \vdash \neg tm_1 \land ... \land \neg tm_n \rightarrow \neg tm \) using the HOL proof rule MATCH_MP to obtain the theorem \( \vdash \neg tm \).

Finally, by matching this theorem to the term \( tm \) the theorem \( \vdash \neg tm \) is obtained.

As the reconstruction procedure traverses the list, it produces the theorem that corresponds to the first goal, namely \( \vdash \bot \). By unfolding the definition of \( \bot \), we obtain \( \vdash \bot \) which concludes the refutation proof.

### 3.3 Comparison to MESON

The simplified OCaml code of the core HOL Light’s MESON algorithm as described in [5] is as follows:

```ocaml
let rec mesexpand rules ancestors g cont (env,n,k) = 
  if n < 0 then failwith "too_deep" else
  try tryfind (fun a -> cont (unify_literals env (g,negate a),n,k))
    ancestors
  with Failure -> tryfind (fun rule ->
    let (asm,c), k = renamerule k rule in
    itlist (mesexpand rules (g:ancestors)) asm cont
    {unify_literals env (g,c),n - length asm, k }) rules;;
```

The toplevel mespmeson function proceeds by turning the input formula into a clausal form, making contrapositives (rules) from the clauses, and then repeatedly calling the mesexpand function with these rules using iterative deepening over the number of nodes permitted in the proof tree.

### 4. Experimental Setup and Results

For the experiments we use HOL Light SVN version 199 (September 2014), Metis 2.3, and leanCoP 2.1. Unless noted otherwise, the systems are run on a 48-core server with AMD Opteron 6174 2.2 GHz CPUs, 320 GB RAM, and 0.5 MB L2 cache per CPU. Each problem is always assigned one CPU.

The systems are compared on several benchmarks, corresponding to different modes of use: goals coming from HOL Light itself,
the general set of problems from the TPTP library, and the large-theory problems extracted from Mizar [28]. The first set of problems is important, however since these problems come from HOL Light itself, they are likely naturally biased towards MESON. The Mizar problems come from the two MPTP-based benchmarks: the MPTP Challenge and MPTP2078 [1]. These are large-theory problems coming from a different ITP, hence they do not introduce the implicit bias as the HOL Light problems, while coming from a more relevant application domain than the general TPTP problems.

For HOL Light, we evaluate (with 5 second time limit) on two sets of problems. First, we look at 872 MESON-solved HOL Light goals that were made harder by removing splitting. In this scenario the tactic is applied to a subgoal of a proof, which is a bit similar to the Judgement-Day [3] evaluation used for Isabelle/Sledgehammer, where the goals are however restricted to the solvable ones. Table 1 shows the results. Second, we evaluate on the top-level goals (with their dependencies already minimized) that have been solved with the HOL Light hammer system [11], i.e., by using the strongest available ATPs. This set is important because tactics such as MESON, Metis and now also leanCoP can be tried as a first cheap method for reconstructing the proofs found by the stronger ATPs. The results are shown in Table 2. In both cases, the OCaml implementation of leanCoP performs best, improving the MESON’s performance in the first case by about 11%, and improving on Metis on the second set of problems by about 45%.

Table 1 shows the results of the evaluation on all 7036 FOF problems coming from TPTP 6.0.0, using 10 second time limit. Here the difference to Metis is not so significant, probably because Metis implements ordered paramodulation, which is useful for many TPTP problems containing equality. The improvement over MESON is about 17%. Table 3 and Table 4 show the results on the small (heuristically minimized) and large MPTP Challenge problems. The best version of the OCaml implementation of leanCoP improves by 54% on Metis and by 90% on MESON on the small problems, and by 88% on Metis and 100% on MESON on the large problems. Here the goal directedness of leanCoP is probably the main factor.

Finally, to get a comparison also with the best ATPs on a larger ITP-oriented benchmark (using different hardware), we have done a 10s evaluation of several systems on the newer MPTP2078 benchmark (used in the 2012 CASC@Turing competition), see Table 3 and Table 4. The difference to Metis and MESON on the small problems is still quite significant (40% improvement over MESON), while on the large problems the goal-directedness again shows even more (about 90% improvement). While Vampire’s (version 2.6) SInE heuristic [6] helps a lot on the larger problems [29], the difference there between E (1.8) and our version of leanCoP is not so great as one could imagine given the several orders of magnitude difference in the size of their implementations.

5. Conclusion

We have implemented an OCaml version of the leanCoP compact connection prover, and the reconstruction of its proofs inside HOL Light. This proof-reconstruction functionality can be also used to certify in HOL Light an arbitrary TPTP proof produced by leanCoP, thus turning leanCoP into one of the few ATPs whose proofs enjoy LCF-style verification in one of the safest LCF-based systems. The performance of the OCaml version on the benchmarks is comparable to the Prolog version, while it always outperforms Metis and MESON, sometimes very significantly on the relevant ITP-related benchmarks.

We provide a HOL Light interface that is identical to the one offered by MESON, namely we provide two tactics and a rule. LEANCOPTAC and ASMLEANCOPTAC are given a list of helper theorems, and then try to solve the given goal together (or the given goal and assumptions, respectively). The LEANCOPTAC rule, given a list of helper theorems acts as a conversion, i.e., given a term statement it tries to prove a theorem whose conclusion is identical to that of the term. The benchmarks show that these are likely the strongest single-step proof-reconstructing first-order tactics available today in any ITP system.
