Infection with low numbers of the sea louse
Lepeophtheirus salmonis induces stress-related effects in postsmolt Atlantic salmon (Salmo salar)

D.T. Nolan, P. Reilly, and S.E. Wendelaar Bonga

Abstract: Infection of postsmolt Atlantic salmon (Salmo salar) with three, six, or 10 preadult and adult sea lice (Lepeophtheirus salmonis) per fish resulted in changes to epithelial structure and at sites in the skin and gill, distant from lice attachment and feeding. In the skin, increased apoptosis and necrosis occurred in the superficial epithelial cells and numbers of mucous cells decreased. In the gill, where no lice were found, uplifting of the epithelium, intercellular swelling, and infiltration by leukocytes occurred in filaments and lamellae. High cell turnover of chloride cells was associated with significantly elevated gill Na+/K+-ATPase activities. Serum chloride levels were elevated in the 3 and 6 lice/fish groups, and the serum Na to Cl ratio was lower in all parasitized groups at 5 days. The results indicate that infection with low numbers of the preadult and adult parasite induced changes characteristic of a stress response. In the low- and medium-infested groups, homeostatic recovery had occurred by 10 days, but recovery was incomplete in the highly infected group. Thus, 10 lice per fish, which is a low infestation level in nature, is stressful and creates a long period during which the overall condition of the skin and gill epithelia may render the fish susceptible to secondary infections.

Introduction

The sea louse Lepeophtheirus salmonis is a caligid copepod that is an ectoparasite of salmonids in seawater. This species is an economically important parasite of sea-farmed salmonids that frequently causes serious disease throughout the Northern Hemisphere (Wootten et al. 1982; Pike 1989).

In wild stocks, this species is normally present in low numbers (i.e., from 10 parasites/fish upwards) on wild fish (Berland 1993; Holst et al. 1993); however, under certain conditions, epizootics can occur (Wootten et al. 1982; Tully et al. 1993; Johnson et al. 1996).

Lepeophtheirus salmonis has a direct life cycle (i.e., no intermediate host) consisting of 10 stages. These include two planktonic naupliar stages, one infectious copepodid stage, and seven on-host stages (four chalimus, two preadult, and one adult) (Wootten et al. 1982; Albright and Johnson 1991b). Numerous studies have investigated aspects of the life cycle, population dynamics, and ecology of L. salmonis in relation to environmental factors (Ritchie et al. 1993; Heuch et al. 1995; Johnson et al. 1996). However, remarkably few studies have examined the nature of the host-parasite relationship. Tissue responses at the site of attachment and feeding, as well as copepodid distribution and load...
on the body of the fish, have been investigated (Jones et al. 1990; Johnson and Albright 1992a; Jonsdottir et al. 1992). Physiological effects following experimental infection of postmolt Atlantic salmon (Salmo salar) with large numbers of L. salmonis have only recently been reported (Grimnes and Jakobsen 1996), and these effects include disturbance of hydromineral balance and mortality attributed to the development of subadult and adult stages of the lice.

One key factor that can affect the health status of fish and increase susceptibility to disease is stress (Pickering et al. 1989; Wedemeyer 1997). While the topic of stress in fish is complex and many of the mechanisms involved are not yet fully understood, cortisol and the catecholamines are crucial in mediating the integrated stress response (see review by Wendelaar Bonga 1997). Salmonids intensively raised in aquaculture are known to have high stress levels, and these can be compounded by aquaculture practices such as transport, grading, and routine maintenance (Barton and Iwama 1991), increasing susceptibility to disease, including ectoparasites. Johnson and Albright (1992b) have shown that intraperitoneal administration of cortisol influenced the salmonid host-parasite interaction and increased susceptibility of coho salmon (Oncorhynchus kisutch) to experimental infection with L. salmonis by suppressing inflammatory response and epithelial hyperplasia in skin and gills.

The skin and gills of a fish are covered by complex epithelia comprising several layers of living cells that are continuous over the body surface (Iger et al. 1995; Nolan et al. 1998). They form the first barrier between the external and the internal environment and are protected with a chemically and functionally complex mucus coat that is discharged by specialized mucous cells in the epidermis (Shephard 1994). The teleostean epidermis is apparently influenced by a number of endocrine factors (Pottinger and Pickering 1985; Iger et al. 1995) and shows characteristic changes in fish exposed to stressors. It has been proposed that salmonids probably die from osmoregulatory problems caused by adult lice mechanically disrupting the skin (Wooten et al. 1982). Recently, osmoregulatory failure and mortality by developing adult stages have been demonstrated in Atlantic salmon (Grimnes and Jakobsen 1996), yet possible indirect effects of the parasite on the epithelium have not been examined. Such effects will become expressed at locations distant from the feeding and attachment areas and may also affect osmoregulation adversely.

The skin epithelium of fish responds strongly to stressors (Iger et al. 1995; Nolan et al. 1998) and offers good possibilities for evaluating indirect stress effects of ectoparasites on the host fish. Several responses, such as increased apoptosis of branchial chloride cells and the pavement cells of the skin, have been shown to be under control of the stress hormone cortisol and will therefore also occur in areas not affected directly by the parasites, including the gills. These stress parameters also allow any relationship between the effects of sea lice and susceptibility to secondary infection to be established through examination of the skin and gill epithelia. The direct tissue damage caused by parasite grazing and indirect epithelial effects and immunosuppression offer opportunities for invasion by secondary pathogens if the overall integrity of the epithelium is compromised during, or remains compromised beyond, this period. These effects may disrupt hydromineral balance and can be assessed by measuring blood ion levels and the activity of key iono-regulatory Na+/K+-ATPases, such as in the gill.

The objective of the present study was to determine whether infection with low numbers of adult and preadult L. salmonis induced a stress response in the Atlantic salmon. We studied parameters in the skin and gill (ultrastructure through light and electron microscopy, as well as gills Na+/K+-ATPase) coupled with blood parameters (serum sodium, chloride, calcium, protein, and urea), to reveal the presence of a stress response.

Materials and methods

Experimental setup

Four groups of 40 seawater-adapted Atlantic salmon (200–250 g body weight) were placed in 400-L circular green plastic holding tanks at the Buntry research facility of the National Aquaculture Development Centre, Cork, Ireland. The tanks were provided with a constant supply of temperature-controlled seawater at 15°C under a 12 h light : 12 h dark photoperiod. After 3 weeks of acclimation, three groups were infected with 120, 240, or 400 subadult and adult L. salmonis of both sexes to achieve initial infection levels of 3, 6, and 10 lice/fish. Infection was carried out in the evening by pouring seawater containing the parasites into each tank. Seawater only was poured into the control tank. Seven fish from each group were sampled at 24 h, 5 days, and 10 days postinfection (1, 5, and 10 DPI).

Sampling procedure

All fish were killed by concussion at the dorsal part of the head. Blood was collected by needle from the caudal blood vessels, allowed to clot for 24 h at 4°C, and centrifuged to obtain serum. Samples of skin from the rostral part of the head above the nostrils and small pieces from the second gill arches were fixed in Bouin's fixative for light microscopy and 3% glutaraldehyde buffered in sodium cacodylate (0.09 M, pH 7.3) with postfixation in 1% osmium tetroxide in the same buffer for electron microscopy (Iger et al. 1995). The samples were taken from areas where the parasites were not attached or where no indications of previous feeding activity could be observed. Another series of head skin samples were
Fig. 2. (A) Upper epidermis of skin from control *S. salar*. The pavement cells (p), showing microridges at the upper cell limits (arrows), form the interface with the water. Little intercellular spacing occurs and the epithelium has good structural integrity. m, mucous cell. Scale bar = 5 μm. (B) Upper epidermis of skin from *S. salar* at 1 DPI with *L. salmonis* (3 parasites/fish) taken from an area where there was no parasite attachment. Intercellular spaces are visible (asterisks) and the integrity of the epithelium is disrupted. A discharging mucous cell (m) can be seen. Scale bar = 5 μm. (C) Upper epidermis of skin from *S. salar* at 5 DPI with 3 parasites/fish taken from an area where there was no parasite attachment. Intercellular spaces are not present and the integrity of the epithelium is good. Considerable numbers of electron-dense desmosomes (arrows) are seen at the borders of the filament cells. Scale bar = 5 μm. (D) Upper epidermis of the skin from *S. salar* at 1 DPI with 6 parasites/fish taken from an area where there was no parasite attachment. Many necrotic pavement cells (n) can be seen and intercellular spaces are present (asterisks). Many predischarge mature mucous cells (m) can be seen close to the surface. Scale bar = 5 μm.
taken at locations where parasites were observed and fixed for electron microscopy in the same way. The remaining gills were dissected and the lamellae trimmed from the gill arch, placed in 1 mL of ice-cold buffer (0.3 M sucrose, 20 mM Na2EDTA, 0.1 mM imidazole, pH 7.1 with HCl), and immediately frozen for measurement of Na⁺/K⁺-ATPase activity.

Sample processing
For quantification of mucous cells, Bouin-fixed skin samples from each fish were processed into paraffin blocks and 5-μm sections were cut perpendicular to the plane of the epidermis. Replicate series of sections were stained with periodic acid – Schiff's (PAS) stain to identify total mucous cells and with the Alcian blue (pH 2.5) method to identify acidophilic mucous cells (Blackstock and Pickering 1982). Total numbers of mucous cells were counted in 10 independent 300-μm views from each sample using a calibrated micrometer in the ocular lens of a light microscope, averaged for each fish, and the mean number of cells per millimetre of transverse epidermal section calculated. Gill samples from each fish were processed by sectioning perpendicular to the plane of the lamellae, stained with haematoxylin and eosin, and examined for general morphology by light microscopy.

For transmission electron microscopy (TEM), one replicate set of fixed skin and gill samples from four fish was stained for 2 h in 2% uranyl acetate, dehydrated through an ethanol series, and embedded in Spurr’s resin. Ultrathin sections were cut by diamond knife, collected on 150-mesh copper grids, and contrasted with lead citrate before viewing in a Philips EM 300 transmission electron microscope at 40 kV. For skin, the overall ultrastructure was observed and attention was focused on cellular necrosis (characterized by nuclei with aggregations of chromatin, swelling of the cytoplasmic compartment, and loss of apical microvilli) and apoptosis (characterized by progressive densification of the nucleus, organelles, and cytoplasm, leading to shrinkage and loss of cell–cell contacts between pavement cells and filament cells) (Table 1; Fig. 2B). Mucous cells differentiate in the middle layers of the epidermis and migrate through to the upper layer where they discharge their contents onto the body surface. Low numbers of leukocytes are also present (Table 1).

The skin ultrastructure from the head of parasitized fish by SEM showed the surface to be a continuous sheet of pavement cells (Fig. 1A). Examination by TEM at 1, 5, and 10 DPI revealed several distinct cell populations (Fig. 2A). The most numerous cell type is the filament cell, which is characterized by layers of perinuclear microfilaments. The uppermost layer of cells is differentiated into specialized pavement cells that have apical microvilli (Fig. 2A). Cell–cell contacts between pavement cells and filament cells are maintained by tight junctions and desmosomes. Little intercellular spacing occurs in the epithelium (Fig. 2A). Mucous cells differentiate in the middle layers of the epidermis and migrate through to the upper layer where they discharge their contents onto the body surface. Low numbers of leukocytes are also present (Table 1).

No statistical difference between the counts of cells stained with PAS or with the Alcian blue (pH 2.5) method at any sample point; therefore the total numbers of cells counted from PAS staining are given. There were significantly fewer mucous cells in the nonfeeding areas of the epidermis of infected fish when compared with controls at 1, 5, and 10 DPI (see Table 3).

There were strong effects in the epidermis of fish infected with 3 parasites/fish at nonfeeding sites at 1 DPI (Fig. 2B). Necrotic pavement cells were commonly observed. Increased intercellular spaces and increased incidence of heavily stained desmosomes were typical (Table 1; Fig. 2B). Leukocytes were seen throughout the epidermis and within the intercellular spaces. At 5 DPI, heavily stained desmosomes were very abundant (Fig. 2C). Apoptotic cells were occasionally encountered, but necrosis in the pavement cell layer was reduced. At 10 DPI, the condition of the skin of these fish was slightly recovered compared with 5 DPI (Table 1).

At 1 DPI, the epidermal condition of fish infected with 6 parasites/fish was similar to that of the group infected with 3 parasites/fish (Table 1; Fig. 2D). However, necrosis in the pavement cell layer was more severe, disruption of the underlying cell layers was greater and many predischARGE mucous cells were located in the upper epidermis (Fig. 2D). At 5 DPI, there was an increase in the staining intensity of the desmosomes and the intercellular spacing was reduced (Table 1; Fig. 3A). Various stages of filament cell apoptosis

Fig. 3. (A) Upper epidermis of skin from S. salar at 5 DPI with L. salmosis (6 parasites/fish) taken from an area where there was no parasite attachment. A macrophage (asterisk) engulfs an apoptotic filament cell. Intercellular spaces are absent and numbers of electron-dense desmosomes (arrows) are visible at the filament cell borders. Scale bar = 5 μm. (B) Upper epidermis of skin from S. salar at 1 DPI with 10 parasites/fish taken from an area where there was no parasite attachment. Many necrotic pavement cells (n) can be seen and intercellular spaces are present (asterisks). Numbers of electron-dense desmosomes (arrows) are visible at the filament cell borders and a mature predischarging mucous cell (m) can be seen. Scale bar = 5 μm. (C) Upper epidermis of skin from S. salar at 5 DPI with 10 parasites/fish taken from an area where there was no parasite attachment. Necrotic pavement cells and intercellular spaces (asterisks) still occur. A lymphocyte (l) is present in the pavement cell layer. Numbers of electron-dense desmosomes are visible and a discharging immature mucous cell can be seen. Scale bar = 5 μm. (D) Upper epidermis of skin from S. salar at 10 DPI with 10 parasites/fish taken from an area where there was no parasite attachment. The integrity of the epithelium is restored in this fish. Few electron-dense desmosomes (arrows) are visible. Scale bar = 5 μm.
were observed (Fig. 3A). At 10 DPI, the overall situation was comparable with 5 DPI, with the exception that intercellular spaces were more extensive and necrosis of the pavement cell layer was reduced (Table 1).

The 10 parasites/fish group showed the strongest epidermal effects at all samplings (Table 1). At 1 DPI, there was extensive necrosis of the pavement cell layer, heavily stained desmosomes, and intercellular spaces present (Fig. 3B). At 5 DPI, immature mucous cells could be seen discharging at the surface, and apoptosis and necrosis of the pavement cell were common (Fig. 3C). At 10 DPI, there was some variation in the condition of the epidermis of individual fish. Some individuals still had extensive pavement cell necrosis and intercellular swelling, while others showed good recovery with a well-differentiated and active pavement cell layer and good epithelial integrity (Fig. 3D).

Gill

The external gill structure of uninfected salmon inspected by SEM and TEM was typical for salmonids that we have sampled from aquaculture conditions (personal observation). The filaments had leaflike lamellae arranged alternately on both sides (Fig. 4A). The respiratory epithelium was one cell thick and leukocytes were commonly in the intercellular spaces (Fig. 4B). In the interlamellar areas, populations of mitochondria-rich chloride cells and mucous cells were present (Fig. 4E). Apoptotic chloride cells were seen occasionally, whereas apoptosis and necrosis were uncommon in other cell types (Table 2). The epithelium of the filaments, with the exception of the interlamellar areas, resembled that of the skin, being composed of filament cells, mucous cells, leukocytes, and an apical pavement cell layer with microvilli.

In lice-infected groups, SEM observations showed that the lamellae were swollen and wrinkled (Table 2; Fig. 4C). In TEM observations, the lamellar respiratory epithelium was uplifted and detached from the endothelium of the central blood sinus in many places (Fig. 4D). Both mucous and chloride cells were found on the filaments, as well as on the lamellae. In lice-infected fish, the chloride cells showed an extensive dilated tubular system (Fig. 4F) not observed in control fish (Fig. 4E; Table 2).

At 1 DPI, the lamellae of fish infected with 3 parasites/fish were swollen (Table 2). Mucus discharge was stimulated in the filament, and apoptotic chloride cells were frequently seen in the interlamellar area (Table 2). Apoptotic chloride cells in the interlamellar lost apical contact with the water and were apparently replaced by neighboring new chloride cells. At 5 DPI, apoptotic bodies, the last stage of apoptotic chloride cells, could be observed (Fig. 5A) in addition to other apoptotic stages (Fig. 5B).

The lamellae sampled from fish infected with 6 parasites/fish at 1 DPI were comparable with those of the 3 lice/fish group (Table 2). Mucus discharge was stimulated in the filament epithelium, and intercellular spaces occurred with heavy leukocyte infiltration (Fig. 5C). The chloride cell population and pavement cells in the interlamellar area were also strongly affected, as desmosomes were reduced and apoptotic cells arophied (Fig. 5D). At 10 DPI, the gill structure in this group was comparable with the 3 lice/fish group, with the exception of lamellar swelling, which still occurred (Table 2).

The group infected with 10 parasites/fish showed the strongest lamellar effects (Table 2). Cellular shrinkage and swelling of the lamellar respiratory epithelium were severe (Fig. 5E). At 1 DPI, newly differentiated cells could be seen at the base of the lamella (Fig. 5F). At 5 DPI, many macrophages containing cellular debris (composed mainly of apoptotic bodies) were observed. The high turnover of chloride cells was continuous and observed at 5 and 10 DPI in most fish examined, although there was some variation between individuals at 10 DPI (Table 2).

Blood parameters

Compared with control values, serum sodium was signifi-

The distance between the blood space and the water is increased by epithelial uplifting. Numbers of leukocytes can be seen in the epithelial intercellular spaces (asterisks). Mucous cells (m) and chloride cells (lc) are present on the lamella. Scale bar = 5 μm. (E) Representative TEM of the interlamellar region of gill from *S. salar* uninfected with lice. Many mitochondria-rich chloride cells (c) are present here, as well as mucous cells (m). There are few enlarged intercellular spaces, epithelial integrity is good, and some leukocytes (arrows) and mast cells (mc) can be seen. Scale bar = 10 μm. (F) TEM view of the interlamellar region of gill from *S. salar* at 1 DPI with 10 lice/fish. The tubular systems of the chloride cells are dilated (arrows) and apoptotic chloride cells (a) are present. Scale bar = 5 μm.

**Discussion**

Infection with low numbers of preadult and adult *L. salmonis* had a marked effect on the integrity of the skin and gill epithelia of the Atlantic salmon. This is an indirect effect of the parasite, as it is reported from areas of epithelia where there was no obvious evidence of prior parasite attachment. The results of this study lead to the conclusion that many of the epithelial changes reported are similar to those described for stressors in general (Wendelaar Bonga 1997), including toxins (chemical stressors), handling, and a submissive position in hierarchy. These effects are hormone mediated, as a consequence of the infection causing an integrated stress response in the fish, resulting in increased levels of circulating cortisol and catecholamines. These results demonstrate that the effects of infection with *L. salmonis* can be divided into two distinct categories. The first is a direct effect of parasite attachment and feeding on the body surface, as reported by others (Jones et al. 1990; Johnson and Albright 1992a; Jonadottir et al. 1992; MacKinnon 1993) and confirmed in this study, i.e., direct damage caused by parasite feeding, etc. The second is the indirect effect of the integrated stress response on the integrity of the skin and gill epithelia, including the osmoregulatory consequences in terms of gill Na⁺/K⁺-ATPase, as reported here for the first time.

At nonfeeding sites, infestation with *L. salmonis* caused necrosis in the pavement cells of the skin, increased apoptosis in the inner cell layers of the epidermis, and stimulated mucus discharge. Necrosis is a form of cellular death directly caused by toxic factors and other damaging agents. Paveinent cell necrosis has been reported for a number of toxic chemicals in freshwater (Nolan et al. 1998) and also during seawater adaptation (Wendelaar Bonga and van der Meij 1989; Uchida et al. 1996) and water acidification (Wendelaar Bonga et al. 1990). The necrotic cells were restricted to the pavement cell layer of parasitized salmon, suggesting that a change in the protective role of the mucus may have been a contributing factor, possibly by reduced protection as a result of a reduction in either total mucus coat or a change in mucus composition. The function of the mucus layer on the body surface of the fish and its components and composition have been reviewed, although there is still uncertainty about the involvement of mucus in ionoregulation in fishes (Shephard 1994). Increased mucus secretion in the present study was indicated by the numbers of discharging and predischarge mucous cells seen in TEM and reduced total numbers of epidermal mucous cells in infested fish. Ectoparasites have been shown to reduce numbers of mucous cells in brown trout (*Salmo trutta*) epidermis (Pottinger et al. 1984), and stimulation of mucus discharge is a cortisol-mediated effect in rainbow trout (*Oncorhynchus mykiss*) (Iger et al. 1995).

The deletion of cells from a tissue is achieved by apoptosis, a physiologically controlled process that activates a genetically programmed mechanism that induces death and elimination of a cell. The stimulation of apoptosis in the skin and gill of parasitized fish is typical of the general epithelial response reported in many fishes (Wendelaar Bonga and van der Meij 1989; Nolan et al. 1998) and indicates increased aging, and therefore increased cell turnover, within these epithelia (Wendelaar Bonga 1997). The mechanisms controlling this process are not fully elucidated, but recently, it has been shown in vivo (Iger et al. 1995) and in vitro (Bury et al. 1997) that cortisol promotes apoptosis. The increased apoptosis in skin and gill epithelia of the sea lice infested fish in the present study may result from elevated circulating cortisol levels.

The overall structural integrity of the epithelia was disrupted, as indicated by the presence of widened intercellular spaces. These spaces are believed to be caused by hydrostatic pressure and osmotic forces and are prominent during periods of epithelial cell elimination through necrosis and apoptosis and increased mucus discharge. As numbers of cells are eliminated, the contacts between the remaining cells are reduced and the spaces become infiltrated with leukocytes. The stimulation of leukocyte infiltration and increased epithelial permeability are probably catecholamine-mediated effects (see review by Wendelaar Bonga 1997). The increase in electron density of the desmosomes connecting the epithelial cells of the skin was correlated with parasite infestation. These desmosomes may fortify the epidermis and reduce intercellular swelling. Heavily stained

In the gill, catecholamine action also increases branchial blood flow, resulting in increased gill perfusion and blood pressure (Satchell 1991; Wendelaar Bonga 1997). The lamellar swelling reported in the present study in parasitized fish may reflect the action of high levels of catecholamines released as a result of parasite-induced stress. We are confident that the effects we report in the gills do not result from any direct action of the parasite, as we infected our fish with preadult and adult parasites, while only the copepodid and chalimus stages have been reported to attach to the gills (Johnson and Albright 1992a, 1992b). Inspection of the gills from our infected fish by light microscopy and SEM revealed no parasites or parasite damage to the gills. In addition, at the water temperature in our experiment (15°C), the generation time from egg to infective stage is estimated at 7.4 days (Johnson and Albright 1991a), so if successful reproduction had occurred, the infective stages would have been active shortly before the 10 DPI sample point. This was when the 3 and 6 lice/fish groups (but not 10 lice/ fish group) showed recovery.

Infestation with sea lice increased gill Na/K-ATPase activity and induced chloride cell apoptosis without greatly disrupting hydromineral balance. Elevated cortisol levels in fish stimulate chloride cell differentiation in vitro (McCormick 1995) and improve hypoxoanoregulation in vivo.
The parasites may find this area attractive because the mucus provides a rich food source and preferentially gather there during heavy infestation, when competition between parasites for feeding resources may be high.

In conclusion, infection of postsmolt Atlantic salmon with low numbers of the sea louse *L. salmonis* has marked effects on the epithelia of the skin and gills, both locally in the skin as a result of parasite attachment and feeding (a direct effect) and overall as a result of the stress response of the fish to infection (an indirect effect). Hydromineral balance in the blood is not greatly affected, but increased gill Na\(^+\)/K\(^+\)-ATPase activity indicates that while the epithelial integrity is compromised, a high rate of sodium turnover occurs. The fish could apparently adapt to an initial infection level of 3–6 lice/fish within 10 days, but not to 10 lice/fish. Thus, infestation is stressful and at higher infection levels creates a prolonged period during which the overall compromised integrity of the skin and gill epithelia, as well as stress-related immunosuppression, may render the fish susceptible to secondary infections.

(Madsen 1990; Cornell et al. 1994), as well as inducing chloride cell apoptosis *in vitro* (Bury et al. 1997). Cortisol is a pluripotent hormone whose effects can be advantageous at moderately elevated levels and deleterious at highly elevated levels (Wendelaar Bonga 1997). In parasitized fish in the present study, the infection increased gill Na\(^+\)/K\(^+\)-ATPase activity at 5 DPI in all groups, increased aging of the mature chloride cell, and stimulated differentiation of a new chloride cell population, and these responses may have contributed to the maintenance or restoration of hydromineral balance. At 10 DPI, gill Na\(^+\)/K\(^+\)-ATPase activity and chloride cell apoptosis had returned to control levels in the 3 and 6 lice/fish groups. However, Na\(^+\)/K\(^+\)-ATPase activity and chloride cell apoptosis in the 10 lice/fish group remained above control levels, indicating that recovery was incomplete and that the stress was greater at this infestation level.

The effects on the chloride cells of the 10 lice/fish group were the strongest. These were correlated functionally at 1 DPI with decreased serum sodium and increased urea, total calcium, and protein in this group. Teleosts are ammonioburied much higher infestation levels on considerably smaller fish (median infestation intensity 64 lice/fish at II days and 42 lice/fish at 31 days following infection with *Argulus foliaceus*). We report here the presence of mucous cell lined ducts in the head region of Atlantic salmon, These ducts have not been reported previously, to the best of our knowledge, and we have confirmed the presence of these ducts in other salmonids (*S. trutta* and *O. mykiss*). We propose that, under normal circumstances, these ducts provide a rich supply of mucus to flow back over the body surface. Sea lice infestation of the scaleless head region can be severe (Pike 1989).
