The 2s and 3s electron spin densities at the nuclear site of 57Fe in iron metal were measured by a new technique combining the Mössbauer effect with electron spectroscopy. Ratios \(|\psi_{2s}(0)|^2/|\psi_{3s}(0)|^2 = 0.9937 \pm 0.0015\) and \(1.012 \pm 0.006\) were measured for 2s and 3s shells, respectively. These results are in qualitative agreement with theoretical calculations of the core contributions to the magnetic hyperfine interaction.

The existence of large negative hyperfine fields in transition-metal ions has been successfully explained as due to polarization of core electrons: The exchange interaction between s-shell electrons and, in iron, the unpaired 3d electrons results in different s-electron radial wave functions, depending on whether the spin of the s electrons is parallel or antiparallel to the 3d magnetization. Consequently, there exists a net spin density \(|\psi_{2s}(0)|^2 - |\psi_{3s}(0)|^2\) for each of the s shells of the atom, and in particular, a nonvanishing spin density at the nuclear site which results, via the Fermi contact interaction, in a hyperfine field at the nucleus. This core contribution to the hyperfine field can be written as the superposition of contributions from all the s-electron shells,

\[
H_c = \frac{e}{2} g \mu_S \sum_n \left( |\psi_{ns}(0)|^2 - |\psi_{ns}(0)|^2 \right),
\]

where \(g\) is the electron g factor, \(\mu_S\) is the Bohr magneton, \(S\) is the total spin of the ion, and the expression between brackets is the spin density at the nuclear site that results, via the Fermi contact interaction, in a hyperfine field at the nucleus. This core contribution to the hyperfine field can be written as the superposition of contributions from all the s-electron shells.

In this experiment, use was made of the fact that the probability \(a_{ns}\) for internal conversion of ns electrons is proportional to the ns-electron density \(|\psi_{ns}(0)|^2\) at the nucleus. The M1 decay from the 14.4-keV, \(I=\frac{1}{2}^+\), first excited state of \(57\text{Fe}\) to the ground state, \(I=\frac{3}{2}^+\), proceeds mostly through internal conversion with a total internal conversion coefficient \(\alpha = 8.17 \pm 0.25\). For an \(57\text{Fe}\) nucleus embedded in a ferromagnetic material, the direction of the 3d electron magnetization may be chosen as the quantization axis (Fig. 1). The nuclear transitions \(\Delta m_s = 1\) \((m_l = -\frac{3}{2} - m_H)\),

**FIG. 1.** Energy-level diagram of \(57\text{Fe}\), indicating the \(\Delta m_s = 1\) transitions, and the corresponding changes in angular momentum of the internally converted electrons.
\(-\frac{1}{2}\) and \(\Delta m_s = -1\) \((m_f = \frac{1}{2} - m_s = \frac{1}{2})\) correspond to total angular momentum changes of the emitted internal-conversion electron \(\Delta m_e = -1\) and \(\Delta m_e = +1\), respectively. If the electrons are emitted into a final \(s\) state \(\Delta m_s = \Delta m_s\), where \(m_s\) is the \(z\) component of the spin angular moment, 

\[
\alpha_{ns}(\frac{1}{2} - \frac{1}{2}) \propto |\psi_{ns}^\dagger(0)|^2,
\]

\[
\alpha_{ns}(\frac{1}{2} - \frac{1}{2}) \propto |\psi_{ns}^\dagger(0)|^2.
\]

Thus, the ratio \(R = |\psi_{ns}^\dagger(0)|^2 / |\psi_{ns}^\dagger(0)|^2\) can be determined by measuring the ratio of internal-conversion electrons emitted in the decay of the \(m_f = \pm \frac{1}{2}\) states separately for each of the four \(s\) shells of iron. The probability of emission into a final \(d\) state is less than 10% of the conversion into a final \(s\) state, and such processes were ignored.

A 92%-enriched \(^{57}\text{Fe}\) absorber, 35 \(\mu\)g/cm\(^2\) thick and 1 cm diam, was prepared by evaporation on a lead-free microscope cover glass 0.1 mm thick. The iron film was annealed for 3 h at 450°C in a hydrogen atmosphere and placed at the source position of a solenoid magnetic \(\beta\) spectrometer. The \(m_f = \pm \frac{1}{2}\) states of the \(^{57}\text{Fe}\) nuclei were selectively excited by Mössbauer absorption of 14.4-keV \(\gamma\) rays emitted by a 50-mCi \(^{57}\text{Co}\) (Pd) source, with an active area of 2 mm diam. The source was mounted on an electromechanical drive and located at 2.75 or 4 mm behind the absorber. A lead collimator limited the diameter of the irradiated area of the absorber to 2 mm. A thin-window (25 \(\mu\)g/cm\(^2\) Formvar) Geiger counter was used as the electron detector. The spectrometer field was set for transmission of any one of the \(K\) (6.3 keV), \(L_1\) (13.6 keV), or \(M_1\) (14.3 keV) \(+N_1\) (14.34 keV) electrons. The resolution of the instrument did not allow separation of the \(L_{11+111}, M_{11+111},\) and \(N\) conversion electrons. However, their relative intensity is low \([L_1/L_{11+111} = 10.7, (M_1+N_1)/M_{11+111} = 13.4,\) and \(N_1/M_1 = 0.034]\).\(^5\) The final data were appropriately corrected for the effect of this unpolarized background.

The Mössbauer source was moved periodically in a constant velocity mode as depicted in Fig. 2(a). The source displacement corresponding to this velocity pattern is shown on Fig. 2(b). The electron counting rate was stored on a multichannel analyzer running synchronously with the drive wave form, Fig. 2(c). During \(\frac{1}{2}\) of the period, the velocity corresponded to excitation of the \(m_f = -\frac{1}{2}\) or the \(m_f = +\frac{1}{2}\) levels, at \(v = +5.15\) mm/sec.
TABLE I. Measured spin density of $s$ electrons at the nucleus in iron metal. $\delta_{ns}$

$$= \frac{\left| \psi_{ns}^1(0) \right|^2}{\left| \psi_{ns}^\prime(0) \right|^2} - 1.$$

| Experiment          | $10^3 \delta_{ls}$ | $\frac{\delta_{ls} + \delta_{ls}}{\left| \psi_{ls}^0(0) \right|^2}$ | $\delta_{ls}$ (%) |

* A value of $\delta_{ls} \approx 8\%$ was chosen to extract the pure $3s$ contribution from the present experimental data. There is considerable disagreement both theoretical (Ref. 8) and experimental (Ref. 9) on the actual conduction electron polarization $\delta_{ls}$.

and $v = -5.51$ mm/sec, respectively. The remaining time, the velocity was far from resonance and only background radiation was detected.

When comparing the internal-conversion rates from the $m_J = \pm \frac{3}{2}$ states, corrections have to be made for background and solid-angle effects. The background is due to cosmic rays and photoelectrons from external conversion of source $\gamma$ rays in the absorber. The counting rate was strongly dependent on the displacement of the source because of the small source-absorber distance. To apply the proper background correction, it was therefore imperative to know the relative position of the source with high accuracy. To this end, the radiation scattered nonresonantly at about $90^\circ$ by the absorber was monitored by two proportional counters placed in the plane of the absorber. The scattered intensity was stored in another multichannel analyzer also synchronized to the wave form [Fig. 2(d)]. From these spectra it is possible to determine directly which "channels" correspond to the same source positions for the on- and off-resonant modes. Thus, the background in the on-resonance spectrum can be obtained from the measured off-resonance counting rate corresponding to the same source position. The background subtraction procedure was also checked by measuring electrons of energy higher than that of the $M$ electrons. In this case, the background count was equal to the count obtained at the resonance velocity to an accuracy of $(0.08 \pm 0.13)\%$.

Since in all theoretical calculations the polarization effect in the $ls$ shell is of the order of $10^{-4}\%$, the background-corrected ratio of counting rates at positive and negative velocities measured on the $K$ electrons was used to normalize the ratios measured on the $L_1$ and $M_1$ electrons.

The measurements were carried out for drastically different geometries corresponding to two different source-absorber separations (2.75 and 4.0 mm) and two different frequencies (8.33 and 16.6 Hz). The results were in all cases in statistical agreement. The summary of these data is presented in Table I. We also show the theoretical predictions obtained either with atomic wave functions or from a band calculation.

Finally, as a further test, measurements were also carried out on the decay of the $m_J = \pm \frac{1}{2}$ states. Because of admixture of $\Delta m_J = 0$ transitions, the polarization effect on the intensity ratio of the internal conversion is expected to be $\frac{1}{3}$ that observed for the decay of the $m_J = \pm \frac{3}{2}$ states. The observed effects were $\delta_{ls} = (-0.40 \pm 0.18)\%$ and $\delta_{ls} + \delta_{ls} = (0.52 \pm 0.64)\%$.

This experiment demonstrates the possibility of measuring individual $s$-shell spin densities at the nucleus by a new technique. In spite of considerable statistical errors due to the low efficiency of the particular $\beta$ spectrometer used, it is nonetheless clear that the results support the theoretically predicted sign and order of magnitude of the spin polarization of the $2s$ and $3s$ electrons in iron.

We wish to thank Professor A. Freeman and Dr. R. Watson for many interesting discussions and their continuous encouragement. We also thank R. Tobin Fink for his help in the early stages of the experiment.
