Scintigraphic Detection of Bone and Joint Infections with Indium-111-Labeled Nonspecific Polyclonal Human Immunoglobulin G

Wim J.G. Oyen, Roland A.M.J. Claessens, Jim R. van Horn, Jos W.M. van der Meer, and Frans H.M. Corstens

University Hospital Nijmegen. Departments of Nuclear Medicine, Orthopaedics and Internal Medicine. University of Nijmegen, The Netherlands

The utility of indium-111- (111ln) labeled immunoglobulin G (IgG) to detect infection of bone and adjacent tissues was investigated. Proof of infection was obtained by cultures taken at surgery. All 32 patients showed focally increased uptake on the technetium-99m- (99mTc) methylene diphosphonate (MDP) skeletal scintigraphies. Labeled immunoglobulin correctly identified presence, location, extent and soft-tissue involvement of the suspected inflammatory site. In these patients, focally increasing accumulation was noted over 48 hr. Discrimination between infection and sterile inflammatory lesions was not possible. Two fractures, 6-mo-old, and an aseptic loosening of a total-hip prosthesis were not visualized. Side effects after the immunoglobulin administration were not observed. Radiolabeled immunoglobulin is a new and safe radiopharmaceutical for the investigation of infectious bone and joint disease. The sensitivity of this agent appears at least as high as that of labeled leukocytes. However, labeled immunoglobulin can easily be prepared in every nuclear medicine department.

Infections of bone and adjacent tissues often present a diagnostic and therapeutic problem, making the management of the disease difficult. The available scintigraphic imaging techniques show limitations in diagnosing these infections. This applies especially to patients who have undergone multiple revision operations for chronic osteomyelitis. Technetium-99m-methylene diphosphonate (99mTc-MDP) bone imaging is nonspecific and not suitable to demonstrate the extent of the lesion accurately (1–3). Gallium-67 (67Ga) may accumulate in areas of increased bone turnover and shows modest accumulation compared to indium-111- (111In) labeled nonspecific polyclonal human immunoglobulin G (IgG) (2,4,5). Some authors reported a low sensitivity of 111In-labeled white blood cells (WBC) scintigraphy to detect low-grade infection (2,6). The utility of 99mTc-WBC to detect chronic osteomyelitis has not been established. Above this, time-consuming techniques are required for every WBC labeling method (7,8). Labeling of leukocytes in full blood with 99mTc-colloid has not been sufficiently validated yet (9–11).

Recently, several reports have appeared suggesting the potential utility of 111In-IgG as an imaging agent for detecting focal inflammation. These studies, both in animals and humans have been primarily concerned with soft-tissue, intraabdominal, and vascular infection (4,12–14). Because of the need for better techniques for imaging bone and joint infection, we initiated a study to evaluate the safety and accuracy of IgG scintigraphy in patients with infections of bone and adjacent tissue.

MATERIALS AND METHODS

Radiopharmaceuticals and Imaging Procedures

In all patients routine three-phase skeletal scintigraphy was performed after i.v. injection of 600 MBq 99mTc-MDP. Diethylenetriaminepentaacetic bicyclic anhydride (bicyclic DTPA) was conjugated to human, nonspecific, polyclonal IgG (Sandoglobulin, Sandoz AG, Nuernberg, FRG) according to Hnatowich and colleagues (15). The purified DTPA-conjugated IgG was diluted to 5 mg/ml with 0.15 M acetate (pH = 6.5) and sterilized by membrane filtration. Aliquots of 0.5 ml of the conjugate were radiolabeled with 111In (Indium chloride, Amersham International Ltd., Buckinghamshire, UK) via citrate transchelation. The radiochemical purity was determined by ITLC-SG chromatography (Gelman Laboratories, Ann Arbor, MI) with 0.1 M citrate (pH = 5) as the solvent. The labeling efficiency was always higher than 97%. A dose of ~1 mg of IgG labeled with 75 MBq 111In was injected intravenously either between 2 and 7 days after the...
$^{99m}$Tc-MDP skeletal scintigraphy had been completed, or after the second-phase images of $^{99m}$Tc-MDP scintigraphy were obtained. The latter procedure was followed when operation was scheduled within 72 hr after the patient had been referred to the nuclear medicine department. Scintigraphic images were obtained with a Siemens Orbiter gamma camera connected to a Scintiview image processor (Siemens Inc., Des Plaines, IL). All images were collected in digital format in a 256 $\times$ 256 matrix. Bone images were always obtained with a low-energy parallel-hole collimator (140 keV photopeak, 15% symmetric window). However, when $^{111}$In-IgG was injected after the second phase of the skeletal scintigraphy, the delayed bone images were obtained with a medium-energy parallel-hole collimator (140 keV photopeak, 15% symmetric window). Indium-111-IgG images were acquired at 4, 18–24, and 42–48 hr postinjection for a preset time of 5, 7.5, and 10 min, respectively. Approximately 1,000–1,500 Kcts for the trunk region, 600–750 Kcts for the pelvic region and 80–120 Kcts for the lower limb were collected. A medium-energy parallel-hole collimator (173 keV peak, 15% symmetric window; 247 keV peak, 15% symmetric window) was used. When injected after the second phase of the bone scan, the 173-keV $^{111}$In peak was not used for imaging $^{111}$In-IgG 4 and 18–24 hr postinjection.

All images were interpreted by three observers. The observers were not blinded for clinical information or radiographic images, when available. A definite judgement of the scintigraphic images was reached before any of the verification procedures were performed. The $^{111}$In-IgG images were interpreted with the corresponding bone scintigraphy. An $^{111}$In-IgG scan was interpreted as positive, if focal increasing accumulation could be noted over time. Nonvisualization of the lesion detected by bone scan and/or plain radiograph, or failure to show increasing accumulation was considered to be a negative $^{111}$In-IgG scintigraphy.

Patients

Patients suspected of acute (evidence of infection since one or several days) or chronic (evidence of infection for weeks, months or even years) osteomyelitis or infectious arthritis in whom a $^{99m}$Tc-MDP bone scan was indicated and in whom proof of the infection was likely to be obtained, were eligible for the study. In 22 out of 25 patients suspected of infection, cultures from the focus were obtained within two days after completion of the imaging procedures, either during operation or by needle aspiration. Furthermore, a small number of patients with noninfectious bone disease were studied to get an impression of the specificity of $^{111}$In-IgG scintigraphy. One patient with clinically-cured sternal osteomyelitis was studied. If the attending physician agreed to perform $^{111}$In-IgG scintigraphy, patients were informed about the experimental nature of the imaging procedure. Pregnant and lactating females were excluded from the study. No patient had a history suggestive of IgA- or IgG-deficiency or adverse reaction to previous IgG administration. Informed consent was obtained. The study was approved by the local ethical committee.

Other Procedures

Blood samples were taken from all patients immediately before and, if possible, 2–3 wk after the $^{111}$In-IgG injection for extensive hematologic (full-blood cell count and WBC differentiation) and biochemical (minerals, liver and kidney function, glucose, cholesterol, protein spectrum) assessment. Also qualitative urinalysis was performed. Vital signs were monitored up to 45 min after injection.

In five patients, suspected of infectious bone disease, the relative uptake of $^{111}$In-IgG in the focus compared to the uptake in the contralateral limb was estimated after drawing variable size regions of interest (ROI) on the 42–48-hr images. Similar regions were then drawn over the corresponding areas on the 4- and 18–24-hr images. Before calculating the ratios on the consecutive images, the regions were normalized for slight differences in size of the two regions.

The same procedure was followed for calculating the ratios in five patients suffering from noninfectious bone disease. In case of nonvisualization of a lesion by $^{111}$In-IgG, the placement of the region was guided by the area of increased uptake on the skeletal scintigraphy.

In three patients, a series of blood samples were taken after $^{111}$In-IgG injection in order to estimate the blood clearance of $^{111}$In-IgG.

RESULTS

Thirty-two patients (16 males, 16 females; mean age 52.7 yr, range 23–87 yr) were investigated. Twenty-five patients were suspected of bone and joint infections in 29 lesions. Seven patients were suffering from noninfectious bone and adjacent tissue disease.

The clinical characteristics of the investigated patients, the results of the $^{111}$In-IgG scintigraphy, the verification procedure, and the results of the microorganism cultures are summarized in Tables 1–4. The patients are categorized on the basis of the clinical data available to the observers at the time of imaging. Sinus tract cultures are not included in Table 1 because they may not reflect the causative microorganism involved (16).

Clinical or biochemical side effects of the $^{111}$In-IgG administration were not encountered.

In all 32 patients, the $^{99m}$Tc-MDP skeletal scintigraphy was positive, indicating the site of the skeletal lesions. On the basis of the clinical features, the three-phase bone scan and the plain radiographs, it was possible to make the diagnosis of acute osteomyelitis or infectious arthritis with sufficient confidence. However, in cases of chronic osteomyelitis, bone scan and radiographs could not identify the presence, the degree, and the extent of infection.

Indium-111-IgG identified the 29 sites of inflammation in all 25 patients, suspected of having an infection. Moreover, with $^{111}$In-IgG scintigraphy, we were able to discriminate between osseous and joint infection. The involvement of the adjacent soft tissues could be delineated accurately with help of the $^{99m}$Tc-MDP images. Figures 1, 2, 3, and 4 show the images obtained by $^{99m}$Tc-MDP and $^{111}$In-IgG in four patients. In Figures 1 and 2, plain radiographs also are presented. In case of inflammation, in the first 48 hr a relative increase of

Patients are categorized on the basis of clinical data available to the observers at the time of imaging. Patients were not using antibiotics unless stated.

$^{111}$In-IgG activity was noted at the affected site compared to the same region in the contralateral limb. Figure 5 shows the increasing ratio of activity over time in five individual patients with infection.

In 22 out of 25 patients suspected of infection, cultures from the focus were obtained two days after completion of the imaging procedures. In 20 out of these 22 patients (Nos. 1–15, 19, 21–24), a positive culture was obtained, proving the infectious etiology of their disease (15 patients with chronic osteomyelitis, 2 with acute spondylodiscitis and arthritis, 1 with acute spondylodiscitis, and 2 with acute arthritis).

In two patients (Nos. 20 and 25) with positive $^{111}$In-IgG scans, the cultures were negative. Patient 20 showed clinical evidence of infection after a biopsy, taken from the right ilium because of a chondrosarcoma. The $^{111}$In-IgG scintigraphy showed increased activity near the site of the biopsy. At surgery, a large hematoma was found near the biopsy site. Cultures taken at surgery remained sterile. The location of the hematoma matched with the site of the $^{111}$In-IgG accumulation. In Patient 25 with $^{111}$In-IgG accumulation in the left knee, joint fluid cultures remained sterile. The Gram-stain, however, showed marked leucocytosis. The patient was diagnosed as having a sterile synovitis of the left knee and recovered without further therapy.

At surgery, it appeared that $^{111}$In-IgG correctly identified the presence and localization of the site of inflam-

Patients are categorized on the basis of clinical data available to the observers at the time of imaging. Patients were not using antibiotics unless stated.
FIGURE 1
Patient 4 (23-yr-old female). Complicated left crural fracture at age of 6, elongation procedure lower leg at age of 19 (fibular transplant), non-complicated refracture at age of 21, osteomyelitis since osteosynthesis. Surgery confirmed chronic osteomyelitis. Cultures showed growth of Staphylococcus aureus and epidermidis and beta-hemolytic Streptococcus. Technetium-99m-MDP 3 hr postinjection (A) and 111In-IgG 4 (B), 24 (C), 48 (D) hr postinjection, and plain radiograph (E). The arrows indicate corresponding areas.

FIGURE 2
Patient 5 (29-yr-old male). Femoral fracture at age of 15, elongation osteotomy at age of 23, infection at age of 25, and recently progressively painful hip. At operation a soft-tissue infection and a chronic osteomyelitis of the right femur were found. Cultures showed growth of Staphylococcus aureus. Technetium-99m-MDP 3 hr postinjection (A) and 111In-IgG 4 (B), 24 (C), 48 (D) hr postinjection, and plain radiograph (E). The arrows indicate corresponding areas.
The impression at operation was, that bone, articular and soft-tissue involvement was predicted correctly by the $^{111}$In-IgG scintigraphy.

In three out of 25 patients, clinically suspected of having chronic infectious bone disease (Nos. 16, 17, and 18) no cultures were obtained. These patients had a recent history of recurrent fistulae, thus proving the infectious etiology of the bone disease. In all three patients, $^{111}$In-IgG correctly localized the lesion and demonstrated the soft-tissue involvement in the region of the fistula.

In addition to the 25 cases stated above, we also studied seven patients not suffering from bone and joint infection. Figure 6 shows the ratio between the $^{111}$In-IgG uptake in the lesion and the corresponding area in the contralateral limb in five of these patients without evidence of infection. Patients 26 and 27 with recent tibial fractures (10 days and 3-wk-old, respectively) showed both positive skeletal and $^{111}$In-IgG scintigraphies. Patients 28 and 29 with both ~6-mo-old fractures had a positive $^{99m}$Tc-MDP bone scan. In these two patients, the $^{111}$In-IgG did not show the lesion, resulting in a ratio of ~1. Patient 30 showed evidence of a well-perfused soft-tissue tumour without osseous involvement just above the knee. Initially, the tumour was well visualized by $^{111}$In-IgG, but over time no increasing $^{111}$In-IgG accumulation in the tumour could be noted. Histologic examination showed a haemangioma.

Patient 31, with clinically-cured sternal osteomyelitis, still showed a hot spot in the sternum at scintigraphy with $^{99m}$Tc-MDP. Indium-111-IgG scintigraphy did not reveal the lesion.

Figure 7 shows the scintigraphic images of Patient 32. This patient showed evidence of loosening of the right total-hip prosthesis. There was no evidence of septic loosening. The bone scintigram shows increased uptake in the right acetabular region. The $^{111}$In-IgG around the prosthesis was normal. Cultures taken at surgery showed no bacterial growth.

A relatively high intravascular activity of $^{111}$In-IgG can be noted up to 48 hr. Figure 8 demonstrates the blood clearance in three patients. The slow clearance of $^{111}$In-IgG resulted in a relatively high background activity at scintigraphy.

**DISCUSSION**

Our results indicate that $^{111}$In-IgG is able to identify the location and the extent of infectious bone and joint infections, particularly in the early stages of disease, before the development of osseous lesions. The high specificity and sensitivity of this radiotracer make it a valuable tool in the evaluation of chronic bone infections, where bacterial culture results may be negative or delayed. The ability to visualize soft-tissue involvement and to monitor the response to therapy is crucial in managing these conditions, ensuring appropriate antibiotic treatment and timely surgical intervention when necessary.
disease. This is especially valuable in low-grade, chronic osteomyelitis.

Although \(^{99m}\text{Tc}\)-MDP skeletal scintigraphy is indispensible for rapid localization of the site of the lesion and visualization of the osseous structures, little information can be obtained about soft-tissue involvement and the actual extent and nature of the lesion, since it lacks specificity to discriminate between reactive increased bone turn-over (i.e., bone remodelling) and actual inflammation (1,3,17,18).

In the literature, no definitive view has been reached on the value of \(^{67}\text{Ga}\) scintigraphy and \(^{111}\text{In}\)-WBC imaging in patients with bone infections. Some authors reported about the usefulness of \(^{67}\text{Ga}\) scintigraphy in chronic infectious bone disease (1,19). Others found a higher sensitivity of \(^{111}\text{In}\)-WBC scintigraphy compared to \(^{67}\text{Ga}\) imaging (2,17,20). It has been noted that \(^{67}\text{Ga}\) may accumulate in areas of increased bone turn-over, decreasing the specificity for infection (2,21,22). In rats with artificial muscle infection, the degree of \(^{67}\text{Ga}\) accumulation appeared to be modest compared to that of \(^{111}\text{In}\)-IgG (4,5).

In our limited experience \(^{111}\text{In}\)-IgG did not accumulate locally in the remodelling phase of 6-mo-old fractures and in an aseptic loosening of a total hip prosthesis.

While \(^{111}\text{In}\)-WBC scintigraphy has proven to have a high diagnostic accuracy in acute infections, there is no consensus on the sensitivity of \(^{111}\text{In}\)-WBC imaging in
patients, suffering from chronic osteomyelitis (2, 3, 6, 19, 20, 23–25). In our study, $^{111}$In-IgG identified all patients suffering from chronic osteomyelitis.

A major advantage of $^{111}$In-IgG is the relatively easy and quick preparation of the radiopharmaceutical, when compared to $^{111}$In or $^{99m}$Tc-HM-PAO WBC. When using WBC, 40–50 ml of blood has to be drawn carefully in order to obtain sufficient undamaged leukocytes. Time-consuming, complex, and costly isolation and labeling techniques are required (7, 8). Whereas the preparation of $^{111}$In-WBC in our department requires at least 2.5 hr, labeling of the IgG-DTPA conjugate with $^{111}$In takes only 10 min. In addition, a constant quality of $^{111}$In-IgG is guaranteed. Whereas many smaller nuclear medicine departments have problems with the proper labeling of leukocytes with $^{111}$In, every department should be able to prepare $^{111}$In-IgG when the IgG-DTPA conjugate is available on the shelf. In view of the recent discussion between Mock et al. and Hanna et al., the utility of labeling WBC with $^{99m}$Tc colloid in full blood remains to be established (9–11).

Since oxine is a cytotoxic agent and $^{111}$In may cause radiation damage to long-living T-lymphocytes, the $^{111}$In-oxine dose in labeling WBC is limited (26). As a consequence, relatively long imaging times are necessary to obtain adequate images. In dogs, $^{111}$In-WBC and $^{99m}$Tc-HM-PAO WBCs identified recent, artificially inflicted osteomyelitis in the appendicular skeleton equally well. Whether infection in the axial skeleton can be adequately detected remains to be established (27). Furthermore, it needs to be clarified whether a time span of 24 hr is sufficient to detect low-grade osteomyelitis with $^{99m}$Tc-labeled WBC scintigraphy.

One advantage of $^{111}$In-WBC over $^{111}$In-IgG is the relatively fast blood clearance of $^{111}$In-WBC, resulting in a low background activity. This leads to a relatively good target-to-background ratio when $^{111}$In-WBC accumulation is present. However, the relatively high
background activity of 111In-IgG, even after 24 and 48 hr, does not significantly interfere with image interpretation. In the majority of patients, the best quality images were obtained 48 hr postinjection. However, the focus of infection could very well be delineated after 24 hr. The images obtained 48 hr postinjection, were necessary in some cases to establish the diagnosis of low-grade osteomyelitis and helped to discriminate between hypervascular status and accumulation of 111In-IgG. This differentiation is not relevant in most patients. Imaging up to 24 hr postinjection is in most cases sufficient. Thus, with regard to the half-life of the radionuclide, IgG imaging with 99mTc would be possible.

We are currently comparing the utility of 111In-WBC and 111In-IgG. Results in the first 16 patients, who were investigated with both techniques, suggest that 111In-IgG is at least as potent as 111In-WBC in revealing an inflammatory lesion. However, compared to 111In-WBC a higher degree of uptake in a lesion can be noted when using 111In-IgG.

Since many patients in the study also received an injection of 99mTc-MDP shortly before the 111In-IgG administration, high standard dosimetry was not possible. Preliminary data suggest that the radiation burden to any organ after the administration of 75 MBq 111In-IgG is far less than 50 mGy (5 rad). This is in agreement with other reports (13). Further studies are in progress. Intravenous IgG preparations in gram doses have been a safe therapeutic agent for years. The injection of 1 mg of radiolabeled IgG did not produce any clinical or biochemical side effects. For these reasons, 111In-IgG can be regarded as a safe radiopharmaceutical (13,28).

The mechanism of IgG uptake at the inflammation site has not been fully elucidated yet. On the basis of experiments, using Fab, F(ab)2 and Fc fragments of the complete IgG molecule, it has been suggested that the Fc-portion of IgG is responsible for the concentration at the inflammation site (4,12). Recently, enhanced vascular permeability followed by macromolecular entrapment in the connective tissues was reported as a possible explanation for IgG accumulation (29).

With 111In-IgG, no definite discrimination is possible between infectious and sterile inflammation. In our study, this is demonstrated by the positive 111In-IgG scintigraphy in patients with a hematoma, sterile arthritis, and recent fractures. This also applies to 111In-WBC scintigraphy (3,24,30-32). In case of chronic osteomyelitis, this is of minor importance, since a sterile inflammatory process seems unlikely in an area with recurrent infections. Of major importance is differentiation between increased bone turnover (due to repair process) and persistent infection.

Only 3 out of 32 patients were using antibiotics at the time of imaging. Therefore, no conclusions can be drawn regarding the effect of antibiotics on the outcome of 111In-IgG scintigraphy. Data in the literature suggest little influence of an antibiotic regimen on the outcome of IgG scintigraphy (4).

Fischman et al. reported the usefulness of serial 111In-IgG scintigraphy in, for example, inflammatory bowel disease to assess the cure of the infection (4,13). Whether this holds true for the assessment of infections of bone and joint will be the object of further studies. In our study, a patient with cured sternal osteomyelitis showed a negative 111In-IgG scintigraphy. Also, the specificity of 111In-IgG imaging in skeletal infections has to be determined.

We conclude that with 111In-IgG a safe, easily prepared radiopharmaceutical has become available. We have obtained promising results with regard to the capability of 111In-IgG scintigraphy to localize infectious bone and joint disease. This property is especially valuable for the investigation of low-grade, chronic osteomyelitis.

ACKNOWLEDGMENTS

This study was supported in part by Ortho Biotech, Washington Crossing, NJ, USA.

The authors want to express their gratitude to Mr. Antoi Meeuwis and his staff and to Mr. Wim van den Broek for technical assistance, to J. Albert Lemmens, MD for supplying the radiographs, and to Robert H. Rubin, MD for critically reviewing the manuscript.
