Abstract

Objectives—To evaluate the usefulness of Gram staining and culture of skin lesions in patients with acute meningococcal infections.

Design—Retrospective study.

Setting—Community hospital and intensive care unit of a teaching hospital.

Subjects—51 patients admitted from 1989 to 1993 with proved meningococcal infections and microbiological examination of specimens from skin lesions.

Interventions—Needle aspiration of a skin lesion before start of antibiotic treatment in 26 patients in the community hospital; punch biopsy of skin lesion after start of antibiotic treatment in 25 patients in the teaching hospital.

Main outcome measures—Detection of meningococci by Gram staining of specimens from skin lesions according to category of infection (meningococcaemia, meningitis, meningitis with shock, or septic shock without meningitis).

Results—Bacteria were detected in the specimen from haemorrhagic skin lesions by culture or Gram staining, or both in 32 (63%) patients. The sensitivity of the Gram stain was 51% and did not differ significantly from its sensitivity in detecting bacteria in cerebrospinal fluid. In meningococcaemia, however, a Gram stained skin lesion was significantly more sensitive (72%) than Gram stained cerebrospinal fluid (22%). In patients with meningitis skin lesions gave positive results on staining more often if shock was present. The results for punch biopsy specimens were not affected by antibiotics as Gram staining gave positive results up to 45 hours after the start of antibiotic treatment.

Conclusion—Microbiological examination of skin lesions is informative, especially in patients with sepsis and inconclusive results from cerebrospinal fluid, and may provide a diagnosis in such patients within 45 minutes. It differentiates well between meningitis with and without haemodynamic complications, and the result is not affected by previous antibiotic treatment.

Introduction

Acute infections with Neisseria meningitidis are life threatening, with an overall mortality of about 10%. The clinical manifestations range from meningococcaemia without circulatory impairment to meningitis, meningitis with shock, or septic shock without meningitis. The mortality from meningococcaemia without shock is negligible, from meningitis is 1-5%, and from sepsis is 30-70%. Roughly two thirds of patients who die succumb within 16 hours after hospital admission. These alarming data emphasise the need for a prompt diagnosis.

The presence of skin lesions usually raises the suspicion of a meningococcal infection. In meningococcal meningitis this suspicion is confirmed by the presence of Gram negative diplococci in cerebrospinal fluid on staining, a process that takes less than one hour. In meningococcal sepsis, however, Gram staining of cerebrospinal fluid often gives negative results for meningococci. As cultures of blood and cerebrospinal fluid yield results only after 12-24 hours and other diseases may present with similar lesions, the initial treatment of meningococcal sepsis is often given blind with respect to the causative micro-organism. Yet, a prompt bacteriological diagnosis is one of the prerequisites for saving lives. In 1917 Nettet and Salanier noted the presence of diplococci in a smear of a skin lesion. Later they successfully cultured meningococci from such a lesion. In the following decades this method did not become generally accepted and only a few studies report on it. In 1944 Bernhard and Jordan stated: "We, like many others, were not appreciative of the tremendous value of the stained smear..." Nearly half a century later we believe that this statement is still true for many doctors.

In view of these considerations, we studied retrospectively the diagnostic value of Gram staining samples from skin lesions of patients with meningococcal infections.

Patients and methods

From October 1990 to May 1992, 45 patients with subsequently proved acute meningococcal infections were admitted to St Laurentius Hospital, a community hospital in the south of the Netherlands. Thirty four patients presented with skin lesions. Needle aspiration of a skin lesion was performed in 26 patients (16 females, age range 6 months to 72 years (median 12.5 years)) immediately after they were admitted to the hospital and before any antibiotics were given. Twenty five patients had haemorrhagic lesions and one had a rash.

From 1989 to 1993, 33 patients with life threatening meningococcal infections were referred to the intensive care unit of the University Hospital in Nijmegen. Thirty two had skin lesions. Punch biopsy of a skin lesion was performed in 25 patients (15 females, age range 7 months to 48 years (median 14 years)) some time after their admission to the unit; at the time of biopsy all patients were receiving antibiotic treatment. Twenty four patients had haemorrhagic lesions and one had a macular rash.

Aspiration was performed by the doctor in charge (paediatrician, neurologist, or physician), who inserted a needle into the centre of a petechial spot at an angle almost parallel with the skin. Some of aspirated fluid was put on to a glass slide with a cottonwool bud and...
transported immediately to the nearby laboratory for Gram staining; the remaining fluid was used for culturing. Punch biopsy was performed by a dermatologist. At the laboratory a smear was made by squeezing a part of the dry specimen between two glass slides. The smear was Gram stained, the remaining part was cultured. The complete procedure, from sampling to microscopic examination of the Gram stained specimen, took about 45 minutes.

Patients were retrospectively divided into four groups based on their clinical manifestations. Patients in group A had meningococcemia without meningitis or shock, those in group B had meningitis, those in group C had both meningitis and shock, and those in group D had septic shock without meningitis. Meningitis was defined as a leucocyte count of greater than $10^4 \times 10^5$ in cerebrospinal fluid with a decreased glucose concentration and increased protein concentration or nuchal rigidity, or both. A definitive classification according to these criteria was not possible in three patients who underwent needle aspiration as their leucocyte count was borderline (104, 110, and $121 \times 10^5$) and glucose and protein concentrations were normal with no nuchal rigidity. These three patients were classed as having no meningitis (one in group A and two in group D). Shock was defined as a systolic blood pressure of less than 100 mm Hg in adults, of less than 85 mm Hg in children younger than 14 years, and of less than 75 mm Hg in children younger than 4 years. In four patients who underwent needle aspiration blood pressure was not noted in the medical records, but other signs of insufficient endorgan perfusion were included, such as acute change in mental state without meningitis, metabolic acidosis, increased serum creatinine concentration, and diffuse intravascular coagulation.

Seven of the 26 patients who had needle aspiration were in group A, nine were in group B, three in group C, and seven in group D. Three patients died (one in each of the groups B, C, and D). Ten of the 25 patients who underwent punch biopsy were in group B, four were in group C, and 11 in group D. Three of them (all in group D) died.

**Results**

Table I shows the microbiological results in all 51 patients. Bacteria were detected in the skin lesions of 16 (64% (42% to 82%)) of the 25 patients who underwent needle aspiration, in nine culture gave positive results, and in five culture gave positive results, in only two culture gave positive results. Bacteria were detected in 14 of the 15 patients who underwent needle aspiration, in nine culture gave positive results, and in one only culture gave positive results.

**Discussion**

In four patients who underwent needle aspiration blood pressure was not noted in the medical records, but other signs of insufficient endorgan perfusion were included, such as acute change in mental state without meningitis, metabolic acidosis, increased serum creatinine concentration, and diffuse intravascular coagulation. Seven of the 26 patients who had needle aspiration were in group A, nine were in group B, three in group C, and seven in group D. Three patients died (one in each of the groups B, C, and D). Ten of the 25 patients who underwent punch biopsy were in group B, four were in group C, and 11 in group D. Three of them (all in group D) died.

*Venepuncture and lumbar puncture were performed before antibiotic treatment.
†In one patient lumbar puncture was performed 21 hours after the start of antibiotics; Gram staining of fluid gave positive results and culture negative results.
were detected in all of the Gram stained skin lesions (Fisher's exact test, p<0.001).

Among the 25 patients admitted to the intensive care unit, 16 were referred from other hospitals after a median delay of 6 hours (range 1-59) and nine were transferred from the emergency unit. All received antibiotics before admission. At punch biopsy these patients had been taking antibiotics for a median duration of 6 hours (range 10 minutes to 60 hours).

Table IV shows the microbiological results of the biopsy specimens. Meningococci were cultured from specimens in patients with shock up to 13 hours after the start of antibiotic treatment and detected by Gram stain as late as 45 hours after the start of treatment.

**Discussion**

Our results show the value of needle aspiration or punch biopsy of skin lesions for the prompt diagnosis of acute meningococcal infections. Haemorrhagic skin lesions are considered to be characteristic for meningococcal infections.1 Similar lesions may, however, be encountered in septicaemia due to pneumococci, staphylococci, *Haemophilus influenzae*, *Carpunclophaga canimorsus*, or viral infections as well as in non-infectious diseases. In 10-25% of all meningococcal infections no skin lesions are present.2 8 Skin manifestations vary from an exanthematic rash,9 10 to erythematous maculopapules or haemorrhagic lesions.11 12 Their presence and development mirrors the course of the disease and may be used as a prognostic factor.13 The development within a few hours of numerous, rapidly extending, haemorrhagic lesions is associated with a fulminant course, as is seen in sepsis. Development may be slower in patients with a more protracted course of meningitis.14 15 In our study skin lesions were absent in 11 of the 45 patients (24%) admitted to the general hospital and in one of the 33 patients (3%) admitted to the intensive care unit.

The pathogenesis of skin lesions in meningococcal disease is not well understood. Originally, meningococci were thought to damage the endothelium by their direct presence in capillaries.16 17 The current view is that the generalised Shwartzman reaction is a cytokine primed vasculitis, mediated by the upregulation of adhesion molecules on leucocytes and endothelium.26 27 Meningococci, meningococcal endotoxin, and several cytokines induced by endotoxin are able to induce this process independently. Therefore, skin lesions may develop without the direct presence of bacteria.

We used two different techniques, needle aspiration and punch biopsy, to obtain material from a skin lesion. Needle aspiration is attractive in emergency cases as it can be performed by the attending doctor in an accident and emergency department. The drawback is that the amount of aspirated material is limited, which might increase the risk of false negative results caused by sampling error. Punch biopsy provides more material, yet the sensitivity of both methods examined by Gram staining and culture was similar (respectively 62% and 64%).

Meningococcal meningitis could be detected in skin lesions by one of these methods in 32 (63%) out of 51 patients; 26 (51%) had positive results on staining. For comparison, only reports from the first half of this century are available. Smears gave positive results on staining in 83%, 80%, 68%, and 70% of the patients at admission and in all patients at necropsy.13 18 21 22 Cultures gave positive results in 88%.13 Our lower yield may partly be explained by the preceding use of antibiotics in 25 patients. The duration of preclinical disease and the probably more advanced infection in the older studies also may be important—for example, in the study of Hayne and Brown in 1948 the mean duration of preclinical disease was 3 days compared with 17-1 hours in our study. None of the older studies differentiated between meningococcaemia, meningitis, and sepsis.

We found that skin lesions were particularly informative in patients with meningococcal sepsis. In 14 of these 18 patients diagnosis was not possible from the results of Gram staining of cerebrospinal fluid, whereas Gram staining of skin lesions provided the diagnosis in 12 (86%) of these 14 patients. As it takes 12 to 24 hours for a culture to yield positive results and only 45 minutes to complete Gram staining of a sample from a skin lesion, staining can speed up the diagnosis considerably. Rapid diagnosis is important because in about two thirds of all fatal cases the patients die within 16 hours after admission.14 17 and because additional therapeutic options such as plasma exchange improve outcome only when started at an early stage.16 Prognosis is also improved by prompt antibiotic treatment.16 17 However, antibiotics are often not given early because they might hamper the bacteriological diagnosis. We found that in patients with shock bacteria were visualised in the Gram stained skin lesion in 13 out of 15 patients up to 45 hours after start of antimicrobial treatment and isolated from skin lesions up to 13 hours after start of the antibiotics. Therefore, in patients with suspected meningococcal shock the first antibiotic dose need not be deferred until after the collection of spinal fluid or blood for culturing.

We also found that in patients with meningitis but no shock bacteria were detected in the stained skin lesion only in 16% of the patients, whereas in all seven patients with meningitis and shock the Gram stained skin lesion gave positive results (p<0.001). This suggests that this difference can be used as an additional prognostic sign—that is, a positive result of a Gram stained skin smear of a currently stable patient with meningitis may alert the clinician to haemodynamic deterioration.

New molecular techniques for the rapid diagnosis of infections have been developed28 29 and may be suitable for biopsy specimens from skin lesions, perhaps with a greater sensitivity.

**Conclusion**

We showed that in suspected meningococcal disease Gram staining and culture of haemorrhagic skin lesions are useful diagnostic tools, especially in patients with sepsis. The results from the Gram stain may accelerate
Influence of socioeconomic factors on attaining targets for reducing teenage pregnancies

Trevor Smith

Abstract

Objective—To determine the rate of pregnancy and outcome in teenagers in areas of different socioeconomic conditions, and to assess the implication for achievement of government and local targets in reducing unwanted pregnancies in teenagers.

Design—Records of pregnancies were obtained from hospital discharge files and rates of live and still births and abortions calculated for each postcode sector. Postcodes were grouped by categories of deprivation and by local government district.

Setting—Tayside, Scotland.

Subjects—Teenage girls admitted to National Health Service hospitals for delivery or abortion in 1980-90.

Main outcome measures—Conception in girls aged under 16 by area of residence and relative proportion leading to live births or terminations. Rate of different outcomes in girls under the age of 20 by area of residence.

Results—The pregnancy rate in girls aged under 16 was three times as high, and in all girls under 20 six times as high in the most deprived areas as in the most affluent areas. The proportion of teenage pregnancies ending in abortions was higher in the affluent areas, where two out of three ended in abortion, than in the most deprived areas, where two out of three ended in abortion compared with one out of four in the deprived areas.

Conclusions—Although there was a higher proportion of teenage pregnancies in more deprived areas, the proportion ending in abortion was greater in more affluent areas, possibly due to social and parental pressure.
