Cationic cobalt clusters complexed with water \( \text{Co}^{n+}_n \cdot \text{H}_2\text{O} \) (\( n=6–20 \)) are produced through laser ablation and investigated via Infrared Multiple Photon Dissociation (IR-MPD) spectroscopy. All spectra exhibit a resonance close to the 1595 cm\(^{-1}\) frequency of the free water bending vibration, indicating that the water molecule remains intact upon adsorption. For \( n=6 \), the frequency of this band is blue shifted, but it gradually converges on the free water value with increasing cluster size. In the lower frequency range (200–650 cm\(^{-1}\)) the spectra contain several bands which show a very regular frequency evolution, suggesting that the exact cluster geometry has little effect on the water–surface interaction. DFT calculations are carried out at the OPBE/TZVP level for three representative sizes (\( n=6,9,13 \)) and indicate that the vibrations responsible for the resonances correspond to bending and torsional modes between the cluster and water moieties. The potential energy surfaces describing these interactions are very shallow, making the calculated harmonic frequencies and IR intensities very sensitive to small geometrical perturbations. We conclude that harmonic frequency calculations on (local) minima structures provide insufficient information for these types of cluster complexes and need to be complemented with calculations that provide a more extensive sampling of the potential energy surface.

I. INTRODUCTION

Water is one of the most important chemicals on our planet, playing a role in virtually all aspects of life. Its interaction with metal surfaces is of fundamental importance, in particular for electrochemical and catalytic processes[1–4]. On the molecular level, the study of this interaction translates into seemingly simple questions: what are the binding sites, the binding energy and the structure of the water?

On bulk metal surfaces, water tends to bind in an erect configuration with the oxygen atom pointing towards the surface while the hydrogen atoms are oriented away from it. Intuitively, one would expect the plane of the water dipole to be oriented perpendicular to the surface. However, theoretical studies suggest an alternative binding motif where the water is bound in an atop adsorption site with the O-H bonds directed nearly parallel to the surface[5]. Experimental information can be obtained from the combination of various experimental techniques, such as low-energy electron diffraction (LEED), scanning-tunneling microscopy (STM)[6], or Reflection-Absorption IR Spectroscopy (RAIRS). The number of studies on the interaction of water with cobalt surfaces, while of fundamental interest for important industrial processes as the Fischer-Tropsch synthesis, has

† Anton Pannekoek Institute, University of Amsterdam, Science Park 904, 1098 XH Amsterdam, The Netherlands
thus far been limited; they indicate that water binds molecularly to most smooth crystalline surfaces, but dissociates on defect sites[7–11]. Direct information on the binding orientation of individual water molecules can be hampered by the facile formation of water clusters on the surface, due to the high mobility of water molecules on surfaces. In order to obtain information on the interaction of water molecules to a metal surface, and in particular to well-defined defect sites, the adsorption of water to a metal nanocluster can be studied in the gas phase. Gas-phase experiments on the one hand allow for an unambiguous determination of the number of adsorbed water molecules, where clusters, a class of matter that bridge the atomic to the bulk, are defect sites by definition: the ability to determine cluster size and its geometric motif offers a level of control over defect sites unattainable for bulk studies. The isolation in the gas phase, and in a helium molecular beam environment in particular, allows for the stabilization of collision products that are inaccessible in surface studies.

Studies on the interaction of metal ions with water in the gas phase are ample, an overview is given by Beyer[12]. The adsorption of water on metal clusters has drawn considerably less attention, although the adsorption of water onto aluminum clusters has been extensively studied[13–16]. As cobalt in nanoparticulate form plays an important role as a catalyst in e.g., the Fischer-Tropsch process[17, 18], there has been a large interest in gas-phase studies of the interaction between cobalt clusters and ligands. Shortly after the development of laser ablation sources[19, 20], the reactivity of neutral cobalt clusters towards water and ammonia was investigated using a flow tube reactor[21]. Thermodynamic information on the interaction between charged cobalt clusters and several ligand molecules has been obtained through mass-spectrometric techniques [22–30], but these do not yield structure-sensitive information.

For this, infrared (IR) photodissociation spectroscopy (IR-PD) has proven to be unsurpassed[31]. Especially the use of IR Free-Electron Lasers has enabled such studies down to the far-IR region through the absorption of multiple IR photons (IR-MPD)[32]. Using this technique, the structures of bare cobalt cluster cations Co_n^+ for sizes up to n = 8 were elucidated[33]. IR spectroscopic information has also been acquired for several ligands bound to cobalt clusters [34–38], but for water such information is limited to the atomic cation, either solvated by multiple water molecules [39], or in the UV spectral domain[40]. We here present IR spectroscopic data of cationic cobalt clusters, ligated with one single water molecule. The brightness of the Free-Electron Laser FELIX allows probing of photodissociation down to frequencies of 250 cm\(^{-1}\). This provides access to not just the water vibrations, but also to vibrations between water and cluster, and of the cluster itself.

Density functional theory (DFT) calculations are usually an integral part in assigning molecular structure to IR spectra. The treatment of transition metal clusters with DFT is, however, challenging as the half filled d-shells may give rise to many possible spin states. For the cobalt studies in this work we note earlier DFT studies [41–45] and in particular the work of Gehrke et al. [33] who combined their IR spectral data for cationic cobalt clusters with DFT calculations using the PBE functional[46]. In the current work we use similar computational methods, but focus on the interaction between the cluster and the water molecule.

II. METHODS

A. Experimental

The experiments described in this paper have been performed using a molecular beam instrument which is coupled to the Free Electron Laser for Infrared experiments (FELIX)[47]. Cationic clusters are created by pulsed laser ablation of a cobalt sample rod (Goodfellow, purity 99.99%) using the second harmonic of a Nd:YAG laser (532 nm, Brio Quantel, attenuated to 30 mJ per pulse). The sample is rotated and translated by a stepper motor enabling a homogeneous erosion of the rod. The ablation takes place in a 4 mm diameter flow tube type cluster growth channel in the presence of a helium carrier gas (190 \(\mu\)s, 5-8 bar) that is introduced through a pulsed valve (General Valve, Series 9). The pulsed valve is synchronized to the ablation laser to ensure the highest helium density at the time of ablation. The generated plasma and the carrier gas undergo multiple collisions leading to cluster formation. Neutral, anionic and cationic clusters are created during this process. In order to form cluster-water complexes, a mixture of 1% water vapor in helium is introduced 60 mm downstream into the channel. By adjusting the dosage of the helium-water mixture, it is possible to produce \(\text{Co}_n^+-(\text{H}_2\text{O})_m\) complexes of varying water uptake (m=1-3). In this study we focus only on the adsorption of one water molecule on cationic cobalt clusters. On exiting the flow reactor, the reaction mixture is expanded into vacuum (10\(^{-7}\) mbar) forming a molecular beam. The molecular beam then passes through a 2 mm diameter skimmer (Beam Dynamics, Inc., model 2) to enter a differentially pumped vacuum chamber and is further shaped by a 1 mm aperture upon entering the extraction region of a mass spectrometer in a third vacuum chamber. Here, the clusters interact with the IR laser beam that is aligned collinearly, but counter propagating to the molecular beam. The focus of the IR beam lies about 25 mm before the extraction point, having a diameter of the same order as the molecular beam, thus ensuring that all extracted clusters actually interacted with the IR laser beam.

The IR light is produced by FELIX[47], which produces intense IR light in the 66 – 3600 cm\(^{-1}\) spectral range; for the present experiments, the range of 200 – 1700 cm\(^{-1}\) is used. The FELIX pulse structure consists of macropulses of 10 \(\mu\)s length operating at a repetition
rate of 5 or 10 Hz with a macropulse energy up to 100 mJ. The macropulse consists of a pulse train of picosecond duration micropulses spaced by one nanosecond. The micropulses are transform-limited with a spectral bandwidth that can be adjusted to 0.2-1% RMS of the central frequency; in the current work the bandwidth was kept at 0.3%. A few μs after interaction with FELIX, all clusters are extracted by a set of pulsed high voltage plates into the reflectron time-of-flight mass spectrometer (R.M. Jordan TOF products, Inc.) and detected with a microchannel plate detector. To correct for long term source fluctuations, the experiment is operated at twice the FELIX repetition rate, allowing for the recording of reference mass spectra in between successive FELIX pulses. Whenever FELIX is in resonance with a vibrational mode of a given cluster, the number of detected \( \text{Co}_{n}^+ - \text{H}_2\text{O} \) cations is reduced due to dissociation of the complex.

The IR-MPD spectrum is obtained by monitoring the depletion of \( \text{Co}_{n}^+ - \text{H}_2\text{O} \) cations as a function of IR frequency. Depositions caused by IR-MPD are expressed as the ratio of the number of ions detected under irradiation with FELIX to that in the reference mass spectrum.

B. Theoretical

The Density Functional Theory (DFT) calculations reported here have been performed using the 2013 version of the Amsterdam Density Functional package (ADF2013)[48–50]. Previous calculations for cationic cobalt are based on PBE functional[33, 44, 45] but in the current work we decided to describe the exchange-correlation energy with the OPBE functional, a combination of Handy’s OPTX modification of the Becke exchange functional with the Perdew-Burke-Ernzerhof (PBE) correlation functional[46, 51], as OPBE has been used successfully in determining the right spin states for high spin systems, providing accurate values for the high-spin/low-spin energy splitting for iron complexes[52–55].

The triple ζ-type (TZP) basis set from the ADF basis set library is used in which the 1s-2p core for Co atoms as well as the 1s core for the O atom have been kept frozen. To account for relativistic effects, the zeroth order regular approximation (ZORA) has been used for all calculations[55, 56]. SCF convergence of such high spin systems such as cobalt is difficult, but convergence to \( \text{10}^{-6} \) is possible in practice in combination with high accuracy techniques. In some calculations, a Mobile Block Hessian (MBH) calculation [57, 58] was performed in which relative positions of the cobalt atoms are kept fixed and only the motion of the water relative to the cobalt cluster is considered.

We performed calculations on bare \( \text{Co}_{6}^+ \), \( \text{Co}_{9}^+ \) and \( \text{Co}_{13}^+ \) using the initial starting structures of the lowest energy conformers according to previous studies[44, 45]. For every cluster species, a wide range of spin states has been considered to determine the spin state with the lowest energy. As usual in DFT calculations, we thereby define the spin state by the \( \text{MS} \) value of the Kohn-Sham determinant, which only rigorously corresponds to the exact spin quantum number for the highest possible spin state of the system[59].

Minima were verified by frequency calculations with analytical or numerical second derivatives. All energies reported include zero-point energies of all vibrational modes.

Once the stable geometries and spin states of the bare clusters were established, water molecules were added at several trial positions and the resulting structures re-optimized in a range of spin states around the lowest energy spin state found for the bare cluster. To once again establish whether the resulting structures are true minima, and, more importantly, to be able to analyze the experimental IR spectra, harmonic frequencies were calculated. All IR spectra reported in these paper have been calculated using analytical frequencies. The accuracy of these calculations were checked by running both numerical and analytical frequency calculations: frequencies calculated using both methods differ by less than 5 cm\(^{-1}\). All frequencies presented in this work are unscaled.

For each optimized complex, a Hirshfeld charge analysis [60] is performed to evaluate the nature of \( \text{Co}_{n}^+ - \text{H}_2\text{O} \) bonding. Binding energies are calculated by taking the difference between the energy of the optimized complex and the sum of the unperturbed cluster and water energies, \( E_b = E_{\text{cluster-H}_2\text{O}} - (E_{\text{cluster}} + E_{\text{H}_2\text{O}}) \). This value thus includes the energetic cost of possible cluster and water structural re-arrangements upon adsorption.

III. RESULTS AND DISCUSSION

A. Experiments

Figure 1 shows the experimental IR-MPD spectra of \( \text{Co}_{n}^+ - \text{H}_2\text{O} \) clusters in the 200–700 and 1500–1700 cm\(^{-1}\) spectral ranges for \( n=6–20 \). Spectra have also been recorded in the 700–1500 cm\(^{-1}\) range, but in this range no depletion has been observed. The spectra are presented as the IRMPD intensity \( I_{\text{IRMPD}}(\nu) \) defined by

\[
I_{\text{IRMPD}}(\nu) \sim \frac{1}{\Phi(\nu)} \ln \left( \frac{I_{\text{ir}}(\nu)}{I_{\text{ref}}(\nu)} \right)
\]

where \( I_{\text{ir}}(\nu) \) and \( I_{\text{ref}} \) represent the ion intensities with FELIX on and off, respectively, and \( \Phi(\nu) \) the photon fluence at frequency \( \nu \). Under full power conditions, depletions of up to 90% could be achieved. For the reported measurements a compromise between spectral broadening and band visibility has been found for conditions where a maximum depletion of 60% occurred. The spectra in the 200–700 cm\(^{-1}\) spectral range are multiplied by a factor 4 to increase the visibility of the bands.

The spectra exhibit clear resonances in the two spectral regions with widths of several tens of cm\(^{-1}\), which
is indicative of a multiple-photon excitation process as suggested in previous experiments [61]. To estimate the number of absorbed photons necessary for dissociation, we consider the bond strength of water to cobalt clusters. The bond strength of water to the cobalt ion (Co$^+$-H$_2$O) is measured to be 1.7 eV [24]. While no experimental value is known for clusters, our theoretical calculations on the binding energy of water on Co$^+_n$, $(n = 6, 9, 13)$ (vide infra) predict substantially lower values than for the ion. All are higher than 0.33 eV, implying that absorption of at least two photons at 1600 cm$^{-1}$, and substantially more at lower frequencies is necessary to photodissociate the complex.

It further can be seen that the signal-to-noise ratios reflect the production efficiency: the spectra for the larger clusters are clearly nosier than those in the $n = 6 - 18$ range.

As all cluster sizes exhibit a limited number of bands, and these bands appear to have a reasonably regular evolution with cluster size, we facilitate the discussion of the resonances by denoting these bands $\alpha$, $\beta$, $\gamma$, and $\delta$ as indicated in Figure 1. To guide the eye, the evolution of these resonances with size are indicated by dashed red lines. These red lines have been obtained by fitting the observed bands to a Gaussian lineshape function to obtain the band center and subsequently the band centers fitted to linear (band $\alpha$) and hyperbolic (bands $\beta$ and $\gamma$) functions as shown in Figure 2.

All cluster sizes exhibit a resonance around 1600 cm$^{-1}$, (band $\delta$). This band is indicative for the presence of an intact water molecule as it nearly coincides with the bending vibration of free water at 1595 cm$^{-1}$ [62]. The fact that we have observed depletion for the water bending mode of up to 90% at higher IR fluences, suggests that for the large majority of species investigated here, water molecules remain intact. Nevertheless, we cannot rule out the presence of dissociated water complexes.

The frequency of the $\delta$ band shows a small, but clear size dependence as can be seen in Figure 2. One observes that the resonance frequency for smaller cluster sizes exhibits a marked blue shift, which decreases with the cluster size and eventually turns into a slight redshift. This behavior is consistent with other experiments [63], most notably on V$_n^+$-H$_2$O clusters [64]. The blue shifts for smaller cluster size observed there were attributed to an increase in the H-O-H bond angle caused by a charge transfer induced by the binding of the oxygen atom to the cluster. As a results electron density on the oxygen is transferred towards the cluster thereby weakening the H-O bond strength. As the cluster size increases, the transferred charge is redistributed over a larger surface which is consistent with the decrease in blue shift observed. The red shift for larger clusters, even beyond the free water value of 1595 cm$^{-1}$ is attributed to the weakening of the O–H bonds. We cannot rule out that the multiphoton techniques used in acquiring the data contributes to the shift. To the best of our knowledge, no value for the water bending mode has been reported for binding of water to bulk cobalt.

The bands in the lower frequency range, especially bands $\beta$ and $\gamma$, show a much clearer size-dependence. Unlike for the water bending vibration, where vibrational motion is localized entirely on the water molecule, the vibrations expected in this range involve bond between the cluster and the water molecule. As the reduced mass for this system is size dependent, the resulting vibrational frequencies will change with size. We will later discuss the exact nature of these modes when we compare the
experimental results with the results of the DFT calculations. The regular size evolution of the $\alpha$, $\beta$ and $\gamma$ bands suggest that the modes are not very sensitive to the cluster structure. In contrast, fluctuations in the $\delta$ band indicate a larger sensitivity. A second trend we note is the evolution of the relative intensities for the $\beta$ and most notably the $\gamma$ band: the intensities of these bands are very low as compared to the $\alpha$ band for $n=6$, but gradually become larger and for the $n=12$ cluster dominate the low-frequency range of the spectrum.

Finally, it is of interest to note that cluster sizes $n = 15$ and 16 exhibit frequencies that are not very well fitted by the hyperbolic function shown in Figure 2. Closer inspection of the spectra in Figure 1 hint at a splitting of bands $\beta$ and $\gamma$. The cause of this splitting is unknown. Interestingly, Dillinger et al. [38], report a similar splitting of the $N_2$ stretching vibration for $\text{Co}_n^{+} - N_2$ clusters starting at $n=14$.

### B. DFT calculations

DFT calculations have been performed for $\text{Co}_6^{+}$, $\text{Co}_9^{+}$, and $\text{Co}_{13}^{+}$ complexed with water. In all calculated structures the water molecule is, as expected, bound to the positively charged cobalt surface through binding of the electronegative oxygen to a single Co atom (atop-binding). The orientation of the water dipole is not directed completely orthogonal to the surface, but certainly is not parallel with the surface as was predicted for the bulk [5]. We find dihedral angles $\text{Co} – O – H – H$ on the order of 130-140 $^\circ$. This can be rationalized by the imperfect surface nature of a cluster. All results are collected in Table I.

The nature of the interaction of the cationic cobalt clusters with $\text{H}_2\text{O}$ can be further studied using an Energy Decomposition Analysis (EDA) [65, 66]. In this method, the interaction energy between two fragments is split up into three physical meaningful components: Pauli repulsion ($\Delta E_{\text{Pauli}}$), attractive electrostatic ($\Delta E_{\text{elstat}}$) and orbital ($\Delta E_{\text{orb}}$) interactions. $\Delta E_{\text{elstat}}$ gives the electrostatic interaction energy between the fragments, which is calculated with a frozen electron density distribution in the geometry of the complex. The associated orbital term $\Delta E_{\text{orb}}$ accounts for charge transfer, polarization, and (if applicable) electron-pair bonding. Table II shows the energy decomposition for symmetrized $\text{Co}_6^{+} (O_h)$, $\text{Co}_9^{+} (D_{3h})$ and $\text{Co}_{13}^{+} (D_{4h})$ clusters interacting with water, at the OPBE/TZ2P level of theory. The symmetrization was needed to be able to converge the spin-restricted DFT cobalt clusters that are needed as an intermediate step in the EDA. The final ($\Delta E_{\text{int}}$) includes spin-polarization and are, apart from a small geometrical distortion in the latter, identical to the calculations reported in Table II. From Table II we see that the interaction energy decreases in the order $\Delta E_{\text{int}}^{\text{13-H}_2\text{O}} < \Delta E_{\text{int}}^{9-\text{H}_2\text{O}} < \Delta E_{\text{int}}^{6\text{A}-\text{H}_2\text{O}}$. This is due to the primarily electrostatic nature of the bonding that decreases in strength as the positive charge on the cobalt cluster is spread out over more atoms. There is no simple trend with the number of atoms, however, for the less symmetric $\text{Co}_9^{+}$ cluster all three contributions to the interaction

$E_b = E_{\text{cluster}-\text{H}_2\text{O}} - (E_{\text{cluster}} + E_{\text{H}_2\text{O}})$

$\Delta q = q_{\text{cluster}} - q_{\text{H}_2\text{O}}$

$\Delta E_{\text{orb}}$ includes $\Delta E_{\text{h}}$, $\Delta E_{\text{d}}$, and $\Delta E_{\text{f}}$. $\Delta E_{\text{elstat}}$ gives the electrostatic interaction energy between the fragments, which is calculated with a frozen electron density distribution in the geometry of the complex. The associated orbital term $\Delta E_{\text{orb}}$ accounts for charge transfer, polarization, and (if applicable) electron-pair bonding. Table II shows the energy decomposition for symmetrized $\text{Co}_6^{+} (O_h)$, $\text{Co}_9^{+} (D_{3h})$ and $\text{Co}_{13}^{+} (D_{4h})$ clusters interacting with water, at the OPBE/TZ2P level of theory. The symmetrization was needed to be able to converge the spin-restricted DFT cobalt clusters that are needed as an intermediate step in the EDA. The final ($\Delta E_{\text{int}}$) includes spin-polarization and are, apart from a small geometrical distortion in the latter, identical to the calculations reported in Table II. From Table II we see that the interaction energy decreases in the order $\Delta E_{\text{int}}^{\text{13-H}_2\text{O}} < \Delta E_{\text{int}}^{9-\text{H}_2\text{O}} < \Delta E_{\text{int}}^{6\text{A}-\text{H}_2\text{O}}$. This is due to the primarily electrostatic nature of the bonding that decreases in strength as the positive charge on the cobalt cluster is spread out over more atoms. There is no simple trend with the number of atoms, however, for the less symmetric $\text{Co}_9^{+}$ cluster all three contributions to the interaction

![Figure 3](image-url)
energy are relatively small leading to an energy in between those of the other two. Comparing the very symmetric Co$_6^+$ and Co$_{13}^+$ clusters we see that the drop in charge on the frontier cobalt atom from 1/6 e to about 1/13 e correlates well with the factor 2 decrease in interaction strength. This primarily electrostatic nature of the bonds is also confirmed by a Quantum Theory of Atoms in Molecules (QTAIM) analysis.

In Bader's topological analysis[67], the nature of bonding is analyzed in terms of the properties of electron density and its derivatives. The Laplacian of electron density at the BCP, $\nabla^2 \rho(r)$, is related to the bond interaction energy by local expression of virial theorem $(1/4 \nabla^2 \rho(r) = 2G(r) + V(r)/r)^4$ [68]. The sign of $\nabla^2 \rho(r)$ at a BCP is determined by which energy is in excess over the virial average of 2:1 of kinetics to potential energy. In covalent interactions, the charge density at the BCP is tightly bound and compressed over its average distribution. The kinetic energy density is dominant and $\nabla^2 \rho(r)$ is positive at the BCP. The computed electron density ($\rho(r)$) and Laplacian ($\nabla^2 \rho(r)$) at the BCPs of selected Co$_n^+$–H$_2$O bonds are presented in Table II. The positive value of $\nabla^2 \rho(r)$ at the BCPs, indicates that this interaction should indeed be classified as an electrostatic type of bonding. The magnitude of electron densities at the BCPs furthermore correlates well with the trend in interaction energies.

$Co_6^+–H_2O$

For Co$_6^+$, the two lowest-energy isomers have been investigated: a tetragonal bipyramid (structure 6A) and a capped trigonal bipyramid (structure 6B). Geometries have been taken from Gehrke et al. [33]. For structure 6A, the lowest energy is found at a spin state of $M_S = 15/2$ having bond lengths ranging from 2.24-2.33 Å. The same geometry with a spin state of $M_S = 13/2$ is found at 0.23 eV higher in energy and slightly shortened bond lengths. Structure 6B is found at 0.79 eV with a spin state of $M_S = 13/2$. These calculated results are in good agreement with previous DFT studies[33, 44, 45].

Due to its highly symmetric shape, only one water adsorption site on the surface has been calculated for structure 6A. The addition of water onto 6A strongly reduces the energy difference between the lowest spin states: the energies of 6A–H$_2$O complexes with $M_S = 13/2$ and $M_S = 15/2$ are almost identical (0 and 0.03 eV, respectively). This is caused by substantially larger binding energy of 0.83 eV for water on the $M_S = 13/2$ surface against 0.56 eV on the $M_S = 15/2$ surface.

For the capped trigonal bipyramid (6B), several water adsorption sites (6B-1, 6B-2 and 6B-3) have been tested (see Figure 3). The lowest energy structures are all found for a spin state with $M_S = 13/2$. In absolute terms, they are all found at energies of 0.7-0.85 eV above that of the 6A-water complex. It is further noteworthy that 6B-1 and 6B-2 relax into 6A-water on the $M_S = 15/2$ surface, as does the bare cluster itself.

The calculated spectra for selected structures are shown together with the experimental results in Figure 3. The calculated IR spectra have been convoluted with a Lorentzian lineshape function with a 15 cm$^{-1}$ width. The experimental spectrum of Co$_6^+$–H$_2$O shows four distinct peaks centered around 331, 501, 590 and 1614 cm$^{-1}$. The $\alpha$ and $\delta$ bands are the most intense and have a width of 68 cm$^{-1}$ and 26 cm$^{-1}$ (FWHM), respectively. The $\beta$ and $\gamma$ bands are much weaker with associated widths of 45 cm$^{-1}$ and 35 cm$^{-1}$, respectively.

All calculated IR spectra predict a number of vibrational modes below 300 cm$^{-1}$ with IR intensities less than 20 km/mol and associated with internal cluster vibrations. Each calculated spectrum is dominated by two very intense bands: the water bending vibration close to 1600 cm$^{-1}$, and the water wagging vibration. The line position of the latter varies considerably for 6A, ranging from 282 cm$^{-1}$, and for 6B$–\alpha$ and 6B$–\delta$ bands are the most intense and have a width of 68 cm$^{-1}$ and 26 cm$^{-1}$ (FWHM), respectively. The $\beta$ and $\gamma$ bands are much weaker with associated widths of 45 cm$^{-1}$ and 35 cm$^{-1}$, respectively.

The line position of the latter varies considerably for 6A, ranging from 282 cm$^{-1}$, and for 6B$–\alpha$ and 6B$–\delta$ bands are the most intense and have a width of 68 cm$^{-1}$ and 26 cm$^{-1}$ (FWHM), respectively. The $\beta$ and $\gamma$ bands are much weaker with associated widths of 45 cm$^{-1}$ and 35 cm$^{-1}$, respectively.

Although in agreement with the experimental observation that each calculated spectrum displays a strong band, the overall match between calculated and observed spectra in the 200–600 cm$^{-1}$ spectral range is not very good. The observed mismatch in predicted and observed frequency of the strong band should not be of too much concern: in most theoretical calculations, the harmonic frequencies reported are typically overestimated in comparison to observed values. This discrepancy is attributed to the fact that the theoretical treatment does not take anharmonicity into account. In most cases, the discrepancies are found to be uniform and can be corrected for by empirical scaling factors, so that a good agreement between theory and experiment can be obtained[69]. In the present case, the concern is rather that none of the calculated spectra exhibits the reasonably intense bands $\beta$ and $\gamma$. Although the calculations predict bands to the blue of the $\alpha$ band, they are very weak and their frequency does not match the experimen-

FIG. 4. Comparison of the experimental spectrum of Co$_6$$^+$$-$H$_2$O to theoretical spectra for structure 6A calculated with different theoretical methods.

tally observed frequencies. Of course, the signal-to-noise ratio for the β and γ bands is not as good as for the α band, but their visibility for larger cluster sizes is much better, and calculations do not predict these either as will become clear below.

One could speculate that the problem is caused by the density functional that is employed; a common strategy is then to carry out calculations with other functionals as well and check for qualitative differences. In order to do so, we carried out calculations using different functionals for three different spin states of Co$_6$$^+$$-$H$_2$O. We chose the revised Perdew-Burke-Ernzerhof (revPBE) functional in the generalized gradient approximation (GGA) [46] with which the spectral assignment of bare cationic cobalt clusters was performed[33], and the Tao-Perdew-Staroverov-Scuseria (TPSS) functional in the meta-generalized gradient approximation (Meta-GGA)[70]. With the latter we have recently been able to assign the spectra for neutral cobalt clusters[71]. To test whether a dispersion corrected density functional has an influence on the vibrational frequencies, we included calculations with the OPBE functional corrected with the D3 method of Grimme[72]. All calculations make use of the same TZ2P basis set. The results of these calculations are depicted in Figure 4. As in all other figures, no frequency scaling is applied. The results show that recomputed spectra vary substantially in line positions, but not in their failure to predict the relatively high intensities of the β and γ modes. This thus likely to be a general feature of the use of harmonic frequencies calculated at the minima of the potential energy surface.

Based on these calculations we can neither assign our spectrum to a specific structure, nor give a verdict on which of the used functionals is the most accurate. We continue for the moment our use of OPBE for harmonic frequency calculations, but we will later discuss the purported failure of the spectral predictions in more detail.

$Co_9^+$$-$H$_2$O

For our calculations on bare Co$_9$$^+$, we have started from the geometry of the lowest energy structure as predicted by previous theoretical studies[44, 45]. These are the tricapped trigonal prism (9A) and the bicapped pentagonal bipyramid (9B), for both of which a spin state of $M_S = 9$ turns out to give the lowest energies, with 9B less stable by 0.51 eV. Co-Co bond lengths found range from 2.24-2.52 Å for 9A and 2.22-2.35 Å for 9B. Different spin states around this minimum structure have energies about 1 eV higher. Onto these stable structures water is added and the structure is re-optimized for different spin states. The results in Table I show that the interaction of H$_2$O with both 9A and 9B does not change the spin state; the average O–H and Co–Co bond lengths, as well as the H–O–H bond angle, on the other hand increase slightly upon complexation.

The experimental spectrum (top panel in Figure 5) displays four distinct peaks centered around 342, 480, 577 and 1609 cm$^{-1}$. The theoretical spectra exhibit a similar trend as for Co$_6$$^+$$-$H$_2$O: an intense band near 300 cm$^{-1}$ and only weak features to the blue of this band, in clear disagreement with experimental findings. The calculated spectra appear to be less sensitive to changes in spin state than for Co$_6$$^+$$-$H$_2$O; the energy difference between 9A and 9B is substantial with 0.62 eV. Binding energies found for 9A and 9B are 0.64 and 0.57 eV, respectively.

$Co_{13}^+$$-$H$_2$O

Calculations for Co$_{13}$$^+$ have been done using the cluster geometry found by Datta et al. [44]. The most stable structures found have spin states of $M_S = 15$ and
$M_S = 16$, respectively, where the higher spin state is favored by 0.17 eV. The binding energies of water to Co$_{13}^+$ ($M_S = 15$) is computed at 0.52 eV, and that for $M_S = 16$ even lower at 0.34 eV, making the $M_S = 16$ structure the lowest in energy, albeit by a meagre 0.01 eV. Both binding energies are substantially lower than the binding energies found for the Co$_6^+$ and Co$_9^+$ clusters. This can be rationalized taking into account that in the icosahedral structure each atom is coordinated towards five neighboring atoms. It also implies that at 1600 cm$^{-1}$ only two photons need to be absorbed to induce dissociation.

The experimental spectra (Figure 6) follow the trend observed before: an intense band at 343 cm$^{-1}$, and at least two bands at frequencies between 400 and 600 cm$^{-1}$ (band centers 438 and 552 cm$^{-1}$, respectively). Interestingly, we now find that the band at 552 cm$^{-1}$ is more intense than the band we tentatively assign to the wagging vibration at 343 cm$^{-1}$. The calculated spectra for different spin states are nearly identical apart from a substantial shift of the frequency of the wagging vibration. As observed before, the predicted intensities of the higher-frequency modes do not agree with the experimental observations.

**Discussion**

The results from the previous sections show that the harmonic calculations do not provide a qualitatively correct description of the observed spectra: where the predicted frequencies and IR intensities for the water bending mode (around 1600 cm$^{-1}$) are quite reasonable, those predicted for the water–cluster vibrations are inadequate, as they simply fail to reproduce the number of intense IR bands observed in the experiments. To rule out any effects from the choice of functional, we carried out the same calculations for Co$_6^+$–H$_2$O using two different functionals. The results suggest that OPBE is not performing worse than either OPBE-D3, revPBE or TPSS: there are differences in frequencies and intensities, but neither method offers a better prediction for the intensities of the $\beta$ and $\gamma$ bands.

All methods reasonably agree on the nature of the vibrations calculated, which are schematically shown in Figure 7. The most intense band is the water libration mode, where the water molecule makes a wagging motion. We tentatively assign the $\alpha$ bands, being the most intense band observed, to this vibration. A second much more definite assignment is the water bending mode to the $\delta$ bands. For the $\beta$ and $\gamma$ bands none of the calculations offer a satisfactory prediction. Frequencies do not match and the intensities are very low. They also give no indication for an increase in intensity with growing cluster size.

One may argue that IR-MPD spectra should not be compared with the (calculated) linear absorption spectrum. It is true that IR intensities are not always represented well, but usually the frequencies are predicted quite accurately. In the present case, the intensities are very different and no clear trend is found in the frequency of modes upon enlarging the number Co atoms in the cluster. Given the regularity in the frequency evolution with cluster size, it is, however, tempting to conclude that the exact cluster geometry is subservient to the Co–O bond involving the single Co atom, and that the cluster size effectively only comes in to modify the reduced mass involved in the vibration.

To test this hypothesis we carry out two types of calculations. In the first we calculate the analytical Hessian to obtain the IR spectrum for Co$_5^+$–H$_2$O, and then calculate the equivalent for isotopically substituted analogues, taking the mass of Co$_6^+$. The result of these calculation are shown in panel a) of Figure 8. As a single atom will also be electronically quite different from a cluster we also repeat this calculation for structure 6A, where we show the results of a similar "isotopic substitution" in Figure 8b. In a second type of calculation we employ the Mo-
does therefore not explain the experimental observation. In both cases the change of mass alone barely shift. At the same time, the relative IR intensities predicted either.

α is not responsible for the band, the third band is not expected to be trivial, given the proximity of different spin surfaces.

IV. CONCLUSIONS

We have recorded the IR spectra for cationic cobalt clusters complexed with water molecules Co$_n^+\cdot$H$_2$O (n=6-20) using IR-MPD spectroscopy. These constitute the first spectra of water adsorbed onto transition metal clusters that directly address the vibrations of the water-cluster bond; one earlier study of water adsorbed onto vanadium clusters only investigated the vibration of the water itself[64]. The experimental spectra provide clear resonances in the 200–600 cm$^{-1}$ spectral range that are evolving quite regularly with cluster size.

The deceiving simplicity of the size-evolution of the observed bands is all the more intriguing as the theoretical description using harmonic frequencies at the OPBE/TZP level are accurate for the localized water bending mode near 1600 cm$^{-1}$, but interestingly appear to fail in the low-frequency range. We have investigated whether the use of other functionals OPBE-D3, revPBE or TPSS) improves the description, but found no large improvements. Factors that may play a role in this are a possible overestimation of the coupling strength between water-cluster motions and internal cluster vibrations or a strongly anharmonic shape of the potential well of the
Co-H2O bond.

As the current data are the first that directly probe the interaction between cobalt clusters and water, they can serve as a benchmark for future developments in describing the metal-water bond which is of fundamental importance. At the same time it is clear that extending these types of studies to other metals will further our understanding of such bonds. Such studies are therefore currently being pursued in our laboratory.
