Construction of a Multiwired Molecular Cable of Micrometer Length by a Self-Assembly Process**

Cornelis F. van Nostrum, Stephen J. Picken, and Roeland J. M. Nolte*

The engineering of molecules and molecular systems that can form nanometer-sized structures is currently receiving a great deal of attention.1-3 An interesting challenge is the construction of molecular wires and molecular channels capable of transporting electrons and ions. For example, phthalocyanines substituted with long hydrocarbon side chains have been reported to form conducting mesophases in which the molecules are stacked in columns. Electron conduction within the columns is fast, whereas it is slow between the columns.14,15 In previous papers we have shown that crown ether molecules can be stacked to create ion conducting channels.16,17 Here we describe a novel liquid-crystalline molecule (1) that self-assembles in chloroform solution to form a molecular cable. This cable contains a central wire of stacked phthalocyanines, four molecular channels built up from stacked crown ether rings and a surrounding hydrocarbon mantle. Isolated cables with molecular thickness and a length of several micrometers can be recognized in electron microscopy images.

Phthalocyanine 1 was prepared from crown ether 12 by a cyclization reaction (see Scheme 1). The crown ether was synthesized from 11, which in turn was assembled from the building blocks 6 and 10. The starting compound for 6 was 3,4-dihydroxybenzaldehyde (2). This compound was alkylated with decyl...
bromide (\(\sim 3\)) and subsequently converted into 3,4-bis(Decoxy)phenol (4) by a Baeyer–Villiger type of oxidation. Treatment of the phenol with Frey's radical[19] under phase transfer conditions yielded 4,5-bis(decoxy)-1,2-benzoquinone (5), which was converted into 1,2-bis(acetoxy)-4,5-bis(decoxy)benzene (6; for characterization see Table 1) by reduction with zinc/acetic acid/acetic anhydride. The overall yield of 6 from 2 was 38%. The synthesis of the second building block 10 was performed using more standard reactions. Catechol (7) was brominated and subsequently alkylated with tetrahydropropyryl (THP)-protected diethylenglycol monochloride to give, after in situ deprotection, compound 9. Reaction of 9 with p-toluenesulfonfonyl chloride gave compound 10 as a highly viscous oil in 42% overall yield (Table 1). The coupling of the two fragments was carried out by first hydrolyzing 6 and subsequently treating the resulting catecholate in situ with 10. The two bromine atoms of 11 were substituted by nitrile groups with copper cyanide in N,N-dimethylformamide (DMF). Finally, the resulting crown ether 12 was converted into phthalocyanine 1 by refluxing in N,N-dimethylaminooctanol (overall yield from 6 and 10 13%). Compound 1 was purified by repeated recrystallization from chloroform. Spectroscopic and elemental analysis were consistent with the proposed structure (Table 1).

Crown ether phthalocyanine 1 showed thermotropic liquid crystalline behavior as was evident from differential scanning calorimetry (DSC), polarizing microscopy, and small angle X-ray scattering (SAXS) measurements. A transition to a highly viscous, birefringent mesophase was observed at 148 °C on heating (\(\Delta H = 130 \text{kJ mol}^{-1}\)). Large hysteresis was observed on cooling: the transition to the crystalline phase occurred at 105 °C. No transition to the isotropic phase was observed below the decomposition temperature of the compound (320 °C). The large number of peaks in the SAXS measurements at room temperature indicated a crystalline phase. In the mesophase at 170 °C an intense peak, corresponding to a spacing of 35.10 Å, and a very broad peak, corresponding to 4.5 Å, were visible. The former peak probably is the (100) reflection of a hexagonal columnar phase with an intercolumnar distance of 40.5 Å.

Generally, alkoxy- and crown-ether-substituted phthalocyanines are highly soluble in organic solvents. Surprisingly, it was only soluble in boiling chloroform and in boiling toluene. A solution of 1 (at a concentration of 7 mg mL\(^{-1}\)) in chloroform formed a gel on cooling. A UV/Vis spectrum of a dilute solution (11 μM) of 1 in chloroform at 50 °C showed a split Q-band at 660 and 700 nm that is typical for nonaggregated metal-free phthalocyanines. However, when this solution was cooled to room temperature a blue shift of the bands and a broadening of the signals was observed, which is characteristic of aggregated phthalocyanine species (Fig. 1).

The structure of the aggregates was elucidated with the help of transmission electron microscopy (TEM). Compound 1 (7 mg) was boiled in chloroform (1 mL), and after the solution had cooled, a drop of the resulting gel was placed on a carbon-coated copper grid. After one minute the grid was blotted dry and shadowed with platinum at an angle of approximately 45°. Two representative TEM pictures are shown in Figure 2. At low magnifications fibers with a length in the order of micrometers, which form a network structure, are observed. At higher magnifications these fibers are seen to consist of bundles of single parallel strands. The thickness of these strands equals the diameter of a molecule of 1 as estimated from CPK space-filling molecular models, that is, 50–60 Å. Several isolated strands can be observed with the same diameter. At lower concentrations of 1 in chloroform, that is, below the gel-forming point, fibers are still present, but they are smaller, and no network is formed.

The conclusion from these experiments is that crown ether phthalocyanine 1 self-assembles into extremely long stacks of molecular thickness, which consist of more than 10⁶ molecules. To the best of our knowledge, evidence for the formation of such large phthalocyanine aggregates has not been reported before. Apparently, the attractive forces between the molecules are so strong that complete solution is prevented at room tempcr-
As shown schematically in Figure 3 a stack of molecules 1 can be considered to be a multiwired molecular cable. In view of its structural resemblance to the crown-ether-substituted phthalocyanine polymers previously studied by us,\(^1\) it is reasonable to postulate that the molecular cable is capable of conducting ions and electrons. Apart from that, the transition of 1 from the solid state to the mesophase is probably accompanied by a change in electronic and ionic conductive properties. We are currently investigating this in detail, as well as the polymerization of the dihydroxysilicon derivative of 1 to give a polymerized molecular cable.

Complexes of Partially Fluorinated Macrocycles with a Metal–Fluorine σ-Donor Bond and Their Suitability as Metal Ion Indicators**

Herbert Plenio* and Ralph Diodone

Even though a rather large number of macrocyclic polyethers is known,\(^1\) only few fluorine-containing crown ethers\(^2\) have been reported, and in most of these all of the hydrogen atoms are substituted by fluorine. As a result of the electron-donating nature of the CF2 units, the oxygen or nitrogen atoms in these polyethers no longer exhibit Lewis basicity and therefore cannot form stable metal complexes. The goal of our research work is the synthesis of macrocycles that have only a few fluorine atoms incorporated into the cyclic structure. Upon complexation of metal ions, the fluorine should act as a “detector,” since the \(^{19}\)F NMR signals shift upon complexation.\(^3\) The high sensitivity, combined with a large signal dispersion and the absence of a natural background make \(^{19}\)F NMR spectroscopy an ideal tool for investigation.\(^4\)

Recently we reported the synthesis of a partially fluorinated \([2.2.2]\)cryptand.\(^5\) This compound forms complexes with metal ions; however, the \(^{19}\)F NMR signals shift only slightly upon complexation, since no direct metal–fluorine contacts are formed. Such an interaction becomes more likely if a carbon–fluorine bond is directed towards the center of the crown ether. The relatively small steric demand of the fluorine atom is not expected to interfere with the binding of metal ions; on the contrary it is hoped that formation of a σ-donor bond between fluorine and the metal ion will increase the stability of the metal complexes.

The building block used for the synthesis of the fluorine-containing macrocycles was 1,3-bis(bromomethyl)-2-fluorobenzene (1), which was treated with tetraethylenglycol, ethyleneglycol, or azacrown ethers to yield fluorocrown ethers (Scheme 1).\(^6\)
