IDENTIFICATION OF Ca\textsuperscript{2+}-ACTIVATED ATPase ACTIVITIES IN EEL GILL PLASMA MEMBRANES—I.

WITH NON-SPECIFIC PHOSPHATASE ACTIVITIES*

G. FLIK,† S. E. WENDELAAR BONGA† and J. C. FENWICK‡

†Department of Animal Physiology, Catholic University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands (Tel: 080-558833) and ‡Department of Biology, University of Ottawa, Ottawa, Ontario, K1N 6N5 Canada

(Received 6 April 1983)

Abstract—1. The characteristics of Ca\textsuperscript{2+}-activated ATPase activities previously often postulated as components for the calcium transporting system in fish gills do not fulfill the requirements of a transport Ca\textsuperscript{2+}-ATPase.

2. The chelation of Ca\textsuperscript{2+} - or Mg\textsuperscript{2+}-ions is a prerequisite for the adenosinephosphate esters to serve as substrate for gill plasma membrane phosphatases.

3. Ca\textsuperscript{2+}-activated ATP hydrolysis results from the activity of a heterogeneous pool of phosphatases located in the plasma membranes of the branchial epithelium, as is concluded from substrate specificity tests and the effects of various inhibitors on these hydrolytic activities.

4. In the present study only non-specific phosphatases could be shown.

INTRODUCTION

Teleost fish, whether in fresh water (FW) or sea water (SW), possess efficient mechanisms to maintain blood calcium levels (Wendelaar Bonga and Van der Meij, 1980). In FW, under normal conditions but especially during periods of starvation, this control probably involves the active transfer of calcium from the ambient medium into the extracellular fluids. Indeed, it is well known that fish can extract calcium from their external environment and there is ample evidence to suggest that the major site for this uptake is associated with the branchial apparatus (Mashiko and Jozuka, 1964a; Berg, 1968). The mechanism of this transfer, however, has not been adequately studied. One of us (Fenwick, 1976, 1979), among others (Ma et al., 1974; Moon, 1978; Ho and Chan, 1980; Doneen, 1981) described the presence in the gills of a Ca\textsuperscript{2+}-activated adenosinetriphosphatase (Ca\textsuperscript{2+}-ATPase\textsuperscript{8}) which, in ouabain-sensitive Na\textsuperscript{+}/K\textsuperscript{+}-ATPase, was presumed to be the enzymic basis for the active transport of calcium through the gills. This presumption was supported by various observations. Most significantly, the influx of \textsuperscript{45}Ca\textsuperscript{2+} in perfused, isolated, American eel gills correlated positively with Ca\textsuperscript{2+}-ATPase activity (Fenwick, 1976; So and Fenwick, 1977). Additionally, the activity of this enzyme was reported to be influenced directly by hypocalcin (Ma and Copp, 1978), a hormone which can markedly influence calcium metabolism in teleosts. Further, the level of enzymic activity varied with ambient calcium concentration (Fenwick, 1978).

However, there are serious difficulties with this thesis. If active transport of calcium occurs in the gills it most likely occurs at the basal or lateral membranes where the calcium moves from an intracellular calcium concentration of about 10\textsuperscript{-7} M into a body fluid calcium concentration of about 3 \times 10\textsuperscript{-3} M. Active transport would not be required to move the calcium from the ambient medium (10\textsuperscript{-4} M) into the intracellular compartment (10\textsuperscript{-3} M). However, the typical apparent affinity (K\textsubscript{m}) of the gill Ca\textsuperscript{2+}-ATPase has been reported as about 0.45 mM Ca\textsuperscript{2+}, a value which is not commensurate with effective functioning at the basal or lateral membrane sites. Secondly, the reported pH-optima for these activities were about 8.0 (Ma et al., 1974; Fenwick, 1976) and were therefore within the favorable range for alkaline phosphatase activities. Thirdly, the Ca\textsuperscript{2+}-stimulated ATP hydrolytic activity, even measured at suboptimal pH's (Fenwick, Ma), exceeded reported Na\textsuperscript{+}/K\textsuperscript{+}-ATPase activity to such an extent that Ca\textsuperscript{2+}-transport rates would surpass expected Na\textsuperscript{+}-transport rates by several orders of magnitude. By the data presented in the literature the...
reverse is indicated (Fleming, 1973). Additionally, there has been no unequivocal evidence published to indicate that ATP is the preferred substrate for the presumptive Ca\(^{2+}\)-ATPase. However, in higher vertebrates this Ca\(^{2+}\)-ATPase has been tentatively identified as an alkaline phosphatase-like activity, instead of an ATPase with characteristics of an ion transporting enzyme. In 1970, Haussler et al. (1970) were the first to report that alkaline phosphatase, Ca\(^{2+}\)-ATPase and much of the Mg\(^{2+}\)-ATPase activities of chick brush border membranes are properties of the same enzyme protein. More support for this idea was given by Oku and Wasserman (1978), who studied these activities in chick intestinal brush borders, and by Hanna et al. (1978, 1979) in their studies on these activities in rat enterocyte plasma membranes.

Recently, Ghijsen and Van Os (1979, 1982), Ghijsen et al. (1980, 1982), Van Os et al. (1980) and Van Os and Ghijsen (1981) showed in a series of studies on the mechanisms of calcium transport in the kidney cortex and gut of rats, that Ca\(^{2+}\)-activated ATPase activity is not homogeneous. To be more specific, they detected two different Ca\(^{2+}\)-stimulated ATP hydrolytic enzymic activities in the plasma membranes of enterocytes. One phosphatase was located on both the brush border and the basolateral membranes, had a predominantly low affinity site for calcium, and was inhibited by theophylline and t-phenylalanine, both of which are specific inhibitors of alkaline phosphatase. The other phosphatase, which was located exclusively in the basolateral membranes, had high affinity for calcium, was not inhibited by alkaline phosphatase inhibitors, but was specifically inhibited by the calmodulin antagonist chlorpromazine. Additionally, they showed that the rate of accumulation of calcium by sealed vesicles of basolateral membranes was an exponent of the activity of high calcium affinity Ca\(^{2+}\)-ATPase and not of the low calcium affinity Ca\(^{2+}\)-ATPase. As a result of these studies they concluded that the low affinity phosphatase was an alkaline phosphatase-like enzyme and that the high affinity phosphatase was the true Ca\(^{2+}\)-ATPase with characteristics of an ion transporting enzyme. This is supported by the observation that rachitic rats show concurrent increases in intestinal calcium absorption, high-affinity Ca\(^{2+}\)-ATP activity and ATP dependent Ca\(^{2+}\)-transport in the basolateral membranes.

Because of the difficulties listed earlier, and the recent evidence for the existence of at least two Ca\(^{2+}\)-dependent phosphatases, we decided to re-evaluate characteristics of the putative teleost gill Ca\(^{2+}\)-ATPase using more rigorous and inclusive criteria to investigate whether the low affinity non-specific phosphatase activity or the high affinity Ca\(^{2+}\)-ATPase activity is the most likely candidate for the energy generating source of the calcium pump in eel gills. To this end we improved the previously reported procedure (Fenwick, 1976) for the isolation of gill plasma membranes. Additionally, we prevented the ATPase activity which might have resulted from mitochondrial contamination by adding as a routine specific mitochondrial ATPase inhibitors to the assay media.

---

**MATERIALS AND METHODS**

Yellow female eels, Anguilla rostrata LeSeuer, were used. The fish used for enzyme characterization studies had an average body weight of 1.7 kg and were obtained in the spring of 1982 from a commercial fish dealer in Quebec City, Quebec, Canada. The eels were held in running dechlorinated Ottawa city tapwater (0.45 mM Ca\(^{2+}\), 12°C) under 16 hr of light alternating with 8 hr of darkness. During the experiments the fish were not fed. The experiments were carried out in the summer of 1982.

**Isolation of plasma membranes**

Animals were quickly anaesthetized in a Tris-buffered (pH 7.4) MS-222 solution (6 g/l). The bulbus arteriosus was cannulated and the branchial apparatus was perfused with ice cold isotonic saline containing heparin (20 U/ml) to remove the blood cells from the gills. Additionally, 0.2 mM phenylmethylsulphonylfluoride (PMSF), a protease inhibitor, was added to the perfusion fluid to increase enzyme recovery. The branchial epithelium was scraped off onto an ice-cold glass plate with a glass microscope slide. The subsequent rapid (3 hr) preparative isolation procedure was carried out at 0-4°C. The collected material (±2.5 g/kg eel) was disrupted gently with a douncer fitted with a loose pestle (20 strokes) in 15 ml of a hypotonic buffer (pH 8.0) containing (mM): NaCl (25), PMSF (0.2) and Hepes/Tris (1). The homogenate was diluted with the same buffer to 75 ml and centrifuged 15 min at 550 g. The pelleted, containing nuclei and cellular debris, was discarded. The supernatant (H\(_s\)) was centrifuged for 30 min at 27K rpm (Beckmann SW 28 rotor) and yielded a pellet containing the membrane fraction (P\(_s\)). The pellet was resuspended with a douncer (100 strokes) in 15 ml of an isotonic buffer containing (mM): sucrose (250), NaCl (12.5), H\(_2\)EDTA (0.5), Hepes/Tris (5, pH:7.5); osmolarity: 300 mosmol/l. H\(_2\)EDTA was added to ensure a leaky vesicle preparation. The suspension was diluted with the same buffer to 30 ml and centrifuged differentially: 1 Kg, 10 min, 10 Kg, 10 min, 30 Kg, 30 min. The final pellet (P\(_p\)) was used as the eel gill plasma membrane fraction. This pellet was resuspended with a douncer (100 strokes) in the basic assay buffer (mM): Tris- HCl (20), NaCl (100), pH, 7.4. To prevent cryodamage of membrane proteins, portions as required for the assays were quickly frozen in liquid nitrogen and stored at -90°C until use.

**Assays and assay media**

**Protein.** Membrane protein was estimated with a commercial reagent kit (BioRad) using bovine serum albumin as reference.

Na\(^{+}/K\(^{+}\)-ATPase. Na\(^{+}/K\(^{+}\)-ATPase was assayed by the method of Bonting and Caravaggio (1963). The incubation was started by the addition of a 20-μl sample of the membrane preparation, containing 10-20 μg protein, to 400 μl medium. The ouabain-sensitive, K\(^{-}\)-dependent activity was calculated as the difference in activities measured in two media. Medium A, yielding total ATPase activity, consisted of (mM): NaCl (100), MgCl\(_2\) (5), H\(_2\)EDTA (0.1), Na\(_2\)ATP (3), KC\(_2\) (12.5) and imidazole (30); pH 7.4. Medium E, yielding the ouabain-insensitive, K\(^{-}\)-independent activity, consisted of medium A without KCl but with added ouabain (1.0 mM). The incubation was performed at 37°C for 10-30 min. The reaction was stopped on ice and by adding 100 μl ice-cold TCA (40%), to determine ATP hydrolysis, the liberated P\(_i\) was estimated as described by Fenwick (1976) with a Technicon auto-analyzer.

**Alkaline phosphatase (pH 10.4)**

Membrane alkaline phosphatase was estimated with a commercial reagent kit (Sigma) for the assay of serum or plasma alkaline phosphatase: p-nitrophenylphosphate.
(p-NPPase) activity was assayed at pH 10.4 in a glycine buffer in the presence of 5 mM Mg²⁺. Eel gut alkaline phosphatase (Sigma, type XIX) served as a reference. Activities were expressed in units eel gut alkaline phosphatase equivalents on basis of p-NP release. After the reaction was stopped with 1 N NaOH, p-NP was measured at 420 nm.

**Succinate dehydrogenase**

Succinate dehydrogenase (SDH) activity was estimated in a medium (pH 8.0) containing (mM): K₂HPO₄/KH₂PO₄ (50), Na₂-succinate (50), sucrose (25), and 1 mg/ml 2-(p-iodophenyl) - 3-(p-nitrophenyl) - 5-phenyltetrazoliumhydrochloride (p-NIT) according to Pennington (1961). The reaction was started by the addition of samples varying from 20–100 µl to 1 ml assay medium and incubations were carried out at room temperature until appropriate pink coloration. SDH activities were determined on the same day as isolation. The reaction was stopped by the addition of 100 µl TCA (40%) and extraction was done with 4 ml ethylacetate. The activity was determined in the organic phase by measuring the absorbance at 490 nm after overnight phase separation at 4°C. Activities were expressed as A₄₉₀/hr mg protein.

Ca²⁺-stimulated phosphatases

The basic medium for Ca²⁺-stimulated phosphatase activities (pH 7.4) consisted of (mM): NaCl (100), ouabain (0.1), Na₂F₃ (5), oligomycin B (5 µg/ml), Tris–HCl (20); disodium salts of ATP, ADP, AMP and p-NPP were used as substrates. Ca²⁺ ~ or Mg²⁺ ~ substrate complexes were prepared by adding equimolar concentrations of the chloride salts of either ion, assuming a 1 : 1 ratio for Me²⁺–chelation by adenosinephosphate-esters (Sapper et al., 1980). Incubations were performed on 20-µl samples in a total volume of 500 µl for 30 min at 25 or 37°C. Substrate hydrolysis was estimated as described for the Na⁺/K⁺-ATPase assay.

In all assays blanks were prepared by adding membrane samples after the reaction was stopped.

Lipophilic inhibitors (chlorpromazine, phenothiazine, R24571) were dissolved in ethanol (100%) and brought to the required concentration in the assay medium (ethanol concentrations did not exceed 0.1%). Membrane samples were preincubated with the desired final concentration of these inhibitors for 15 min at 37°C as suggested for R24571 by Gietzen et al. (1981). Ethanol treated samples served as controls. All assays were performed in plastic tubes.

Water soluble inhibitors (theophylline, 1-phenylalanine, cysteine) were directly dissolved in the assay medium.

**Reagents**

All reagents used were of the highest purity commercially available. Ultrapure water was used in all assays. R24571 was purchased from Janssen Pharmaceutica, Beerse, Belgium. All other chemicals were obtained from Sigma (St. Louis, MO).

**Statistics and calculations**

Values are expressed as mean values±SEM. Statistical analysis of the data was carried out applying Student’s t-test. Significance was accepted with P<0.05 or with P<0.02 when n>4 (a=5%). Apparent K_m-values and V_max-values were calculated by means of Lineweaver–Burk transformation of the Michaelis–Menten equation. Linear regression analysis was based on the least square method.

**RESULTS**

Table 1 shows the percentage recovery and the purification factors for several marker enzymes in the P₁-fraction. Na⁺/K⁺-ATPase was used as plasma membrane marker, while succinate dehydrogenase was taken as a marker for mitochondrial membranes. The P₁-fraction contained about 13% of the initial Na⁺/K⁺-ATPase and underwent a 60-fold purification. Succinate dehydrogenase activity was purified to only a factor of about 1.6 and showed a recovery of about 3.4%. Although a high degree of purification for plasma membranes was obtained as judged by the Na⁺/K⁺-ATPase purification factor, the P₁-fraction still showed mitochondrial contamination. Therefore, we included oligomycin and sodium azide in all our ATPase assays to specifically exclude mitochondrial ATPase activities. Only around 2% of the initial alkaline phosphatase (measured at pH 10.4) was recovered with a purification factor of 0.91. The use of alkaline phosphatase as plasma membrane marker was suggested by Ma et al. (1974) but we conclude this enzyme to be inappropriate in the present study. We prefer the use of Na⁺/K⁺-ATPase as a plasma membrane marker because of its membrane-specificity and its specific ouabain-sensitivity.

**Test for substrate accessibility of the membrane vesicles**

Tween-80 had no significant effect on Na⁺/K⁺-ATPase activity of membrane vesicles of the P₁-fraction (Table 2). As detergent treatment of sealed vesicles should increase Na⁺/K⁺-ATPase activity (Broerhus et al., 1979) as a result of improved substrate accessibility, we concluded that the membrane vesicles of the P₁-fraction were sufficiently leaky and that they did not require detergent treatment for optimal substrate- and ion-accessibility. Apparently the use of EDTA in the isolation procedure secures optimal enzyme activities in this plasma membrane vesicle preparation.

**Effects of storage on Ca²⁺ - or Mg²⁺ -activated ATP hydrolysis**

In Fig. 1 the effects of storage at −90°C on the

Na\(^+\)/K\(^+\)-ATPase activities were used as an indicator of substrate accessibility of the membrane vesicle preparation. Samples were preincubated with Tween-80 (0.1% v/v) at 37°C for 10 min and subsequently incubated for 15 min at 37°C. Similar, buffer preincubated, samples served as controls. Mean values (±SEM) are given for six different samples, with the percentage activity in parentheses.

Specific activities of Ca\(^{2+}\)- or Mg\(^{2+}\)-activated ATP hydrolysis is presented. The Ca\(^{2+}\)-induced ATP hydrolytic activity proved to be more stable than the Mg\(^{2+}\)-induced ATP hydrolytic activity with 61 and 37% of the original activity, respectively, being present after eight days. As a result of the difference in sensitivity towards storage at low temperature, the ratio of Mg\(^{2+}\)-induced ATP hydrolysis to Ca\(^{2+}\)-induced ATP hydrolysis decreased from 0.86 to 0.61 after one day and to 0.53 after 8 days ($P<0.05$). Both curves showed the characteristics of a curve composed of a fast and a slow component. A rapid decrease is observed during the first day of storage, followed by a slower decrease in activity thereafter. Comparable results were presented by Ma et al. (1974) who stored their gill membrane preparations at −20°C. It is tempting to suggest that the difference between Ca\(^{2+}\)- and Mg\(^{2+}\)-induced ATP hydrolysis in sensitivity to storage was a result of the differential inactivation of a heterogeneous enzyme pool present in eel gill plasma membranes.

Activation of adenosinephosphate-ester hydrolysis by Ca\(^{2+}\) or Mg\(^{2+}\)-ions

Significant hydrolysis of adenosinephosphate-esters upon incubation with eel gill plasma membranes was strictly dependent on the presence of Ca\(^{2+}\)- or Mg\(^{2+}\)-ions. This requirement for hydrolytic activity may involve activation of enzymes or a modification of the conformation of the substrates due to the chelation of these ions to adenosine phosphate-esters. The high concentrations of the ions required for maximum activation (5 mM Ca\(^{2+}\) and 5 mM ATP). Specific activities amounted to 60.2±2.8 µmol P/hr/mg protein for 5 mM Ca\(^{2+}\)-ATP, 34.7±8.1 µmol P/hr/mg protein for 5 mM Ca\(^{2+}\)-ADP and 43.1±3.9 µmol P/hr/mg protein for 5 mM Mg\(^{2+}\)-ATP. Mg\(^{2+}\)-concentrations that resulted in half-maximal activation of substrate hydrolysis (calculated with Lineweaver-Burk plots): 78 µM Ca\(^{2+}\) for ATP, 51 µM Ca\(^{2+}\) for ADP and 101 µM Mg\(^{2+}\) for ATP. Mean values of six observations are given.

The combination of ligands with metal ions is given by:

\[ ML_{i-1} + LML_i \rightarrow ML_i + L \]

\[ K_i = \frac{[ML_i][L]}{[ML_{i-1}][L]} \]

\(K_i\)-values are given for media with an ionic strength of 0.1-0.2 mol/l at 20-30°C. Data were collected from: Stability Constants, Special publication No. 17, London, The Chemical Society, 1964.

matic breakdown of the Ca\(^{2+}\)-ATP complex will give Ca\(^{2+}\)-ADP and phosphate as reaction products. If, on the other hand, a surplus of ATP is present relative to Ca\(^{2+}\)-ions, upon enzymatic hydrolysis of Ca\(^{2+}\)-ATP the Ca\(^{2+}\)-ions will migrate from the reaction product Ca\(^{2+}\)-ADP to the free ATP, which leads to a reaction mixture of Ca\(^{2+}\)-ATP, and free ATP and ADP.

Figure 2 shows the effects of different concentrations of Ca\(^{2+}\)- or Mg\(^{2+}\)-ions on ATP or ADP hydrolysis at fixed concentrations of ATP or ADP (5 mM). Maximum activities consistently occurred at equimolar concentrations of divalent ion and ATP or ADP. The \(V_{\max}\)-value for Mg\(^{2+}\)-activation of ATP hydrolysis was 71.5\% of that of the \(V_{\max}\)-value found for Ca\(^{2+}\)-activation of ATP hydrolysis. The \(V_{\max}\)-values for Ca\(^{2+}\)-activation of ADP hydrolysis came to 57\% of the \(V_{\max}\)-values for Ca\(^{2+}\)-activation of ATP hydrolysis. The apparent \(K_m\)-values for Mg\(^{2+}\)- or Ca\(^{2+}\)-induced substrate hydrolysis were 78 \(\mu\)M Ca\(^{2+}\) for ATP, 51 \(\mu\)M Ca\(^{2+}\) for ADP and 101 \(\mu\)M Mg\(^{2+}\) for ATP. ATP-hydrolysis was increasingly diminished at Mg\(^{2+}\)- or Ca\(^{2+}\)-concentrations exceeding the ATP concentrations (2.5 or 5.0 mM).

In Figs 3(a) and (b) and Table 4 the results of substrate-specificity determinations are shown. Ap-

\(K_m\)-values (mM) and \(V_{\max}\)-values (\(\mu\)mol Pi/hr/mg protein) were calculated for individual samples by means of Lineweaver-Burk plots. Calculated \(V_{\max}\)-values were compared with observed \(V_{\max}\)-values. Mean values are given (±SEM) for four different samples. Significance of differences is given in the text.

Fig. 3. Eel gill phosphatase substrate specificity tests. Aliquots of Pi-fractions were incubated with equimolar concentrations of adenosine-phosphate esters and either Ca\(^{2+}\) (left) or Mg\(^{2+}\) (right). Four plasma membrane preparations were tested with six different substrates each. Additionally, curves are shown that represent the difference between the specific activities measured with ATP and ADP, and the difference between the specific activities measured with ADP and AMP. Half-maximal activation concentrations and maximum velocities (calculated with Lineweaver-Burk plots) are given in Table 4. Mean values and standard errors of the mean are given; \(n = 4\).
parent $K_m$-values and $V_{max}$-values were calculated on the basis of incubations of plasma membranes with varying concentrations of equimolar amounts of phosphate-esters (ATP, ADP, AMP or $p$-NPP) and divalent ions ($Ca^{2+}$ or $Mg^{2+}$). $V_{max}$-values for ADP as compared to ATP ($=100\%$) are 55 and 51\% for $Ca^{2+}$ and $Mg^{2+}$ respectively. The $V_{max}$-values for $Mg$-$AMP$ were twice as high as observed for $Ca$-$AMP$ or $p$-NPP in combination with either $Ca^{2+}$ or $Mg^{2+}$. The apparent affinity for $Mg$-$AMP$ and $Mg$-$ADP$ was significantly higher than for $Ca$-$AMP$ or $Ca$-$ADP$.

For the ATP complexes as substrates the calculated and observed $V_{max}$-values differed significantly. This suggested that the results did not fulfill the requirements for a Lineweaver-Burk transformation. This again may indicate that the enzyme preparation is heterogeneous. On the basis of the apparent $K_m$-values in Table 4 it may be expected that, when ATP-complexes are given as substrate, the reaction product $Ca$-$AMP$ will preferably be hydrolyzed to $Ca$-$AMP$ and subsequently $Ca$-$ADP$ to adenosine. As the release of phosphate was measured as an indication for substrate hydrolysis, the $V_{max}$-values were very likely overestimated when ATP or ADP were used as substrates. Therefore, the saturation curves for ATP and ADP hydrolysis were also presented as the differences between ATP and ADP and between ADP and AMP hydrolysis. The differences between the corrected values for $V_{max}$ of ATP and ADP hydrolysis are not significant.

From these observations we conclude that under the conditions described no high affinity $Ca^{2+}$-ATPase can be demonstrated. Instead the observed hydrolytic activities represent non-specific phosphatase activities. We therefore examined the effects of several inhibitors on $Ca$-$ATP$ and $Mg$-$ATP$ hydrolysis in another set of experiments.

Effects of inhibitors on $Ca$-$ATP$ and $Mg$-$ATP$ hydrolysis (Table 5)

Under our assay conditions, up to 10 mM L-phenylalanine (a known inhibitor of gut alkaline phosphatase) had no inhibitory effect on either $Ca$-$ATP$ or $Mg$-$ATP$ hydrolysis. Conversely, theophylline, a more potent inhibitor of alkaline phosphatase (Ghijsen et al., 1980), inhibited significantly more $Ca$-$ATP$ hydrolysis than $Mg$-$ATP$ hydrolysis (23.4 and 14.6\% respectively). Both activities were inhibited by up to 80\% with L-cysteine (10 mM). However, the calculated 50\% inhibition occurred at 2.27 mM cysteine for $Ca$-$ATP$ hydrolysis and 6.08 mM cysteine for $Mg$-$ATP$ hydrolysis (Fig. 4).

R24571, chlorpromazin and phenothiazin have been reported to inhibit calcium transport related high-affinity $Ca^{2+}$-ATPase activities by competition with calmodulin at very low inhibitor concentrations (0.01–1.0 \(\mu M\)) or by affecting the calmodulin-independent basal activities at higher concentrations (1.0–10.0 \(\mu M\)). Maximum inhibition of $Ca$-$ATP$ or $Mg$-$ATP$ hydrolysis occurred at the higher inhibitor concentrations but no significant differences were observed between the effects of these inhibitors at low or high concentrations. $Mg$-$ATP$ hydrolysis was, however, significantly more sensitive (14\% inhibition) towards these inhibitors than $Ca$-$ATP$ hydrolysis (6\% inhibition).

These results confirm that the $Ca$-$ATP$ or $Mg$-$ATP$ hydrolytic activities in eel gill plasma membranes are not homogeneous.

**DISCUSSION**

Four major findings are presented in this paper. (1) $Ca^{2+}$-activated ATPase activities occurring in the...
gills of American eels are located in the plasma membranes of this epithelium. (2) The assay procedures for fish gill Ca\(^{2+}\)-ATPase previously described in the literature, and retested in this study did not allow the determination of a single, specific Ca\(^{2+}\)-ATPase. (3) Eel gill plasma membranes contain more than one type of enzyme that hydrolyzes complexes of Ca\(^{2+}\) or Mg\(^{2+}\)-ions and adenosinephosphate-esters, as indicated by substrate specificity tests and effects of various inhibitors on these hydrolytic activities. (4) These Ca\(^{2+}\)-activated ATPase activities do not represent high affinity, transport Ca\(^{2+}\)-ATPase activity but rather non-specific ‘alkaline’ phosphatase activities.

**Location of Ca\(^{2+}\)- or Mg\(^{2+}\)-activated ATPase activities**

The procedure used for isolating the plasma membranes of eel gills in this study yielded a highly enriched plasma membrane fraction, as indicated by the Na\(^{+}/K\(^{-}\)-ATPase specific activities, with only minor mitochondrial contamination. To exclude any interference of mitochondrial ATPase activities, oligomycin and sodium azide were routinely added to the assay media. We therefore conclude that the observed Ca\(^{2+}\)- or Mg\(^{2+}\)-activated ATPase activities reside in the plasma membranes of the gill epithelium. But we do acknowledge that a portion of these activities may have originated from enzyme activities of endoplasmatic reticulum origin as we did not screen for marker enzyme activities for these membranes during the isolation procedure. The activation curves observed for ATP hydrolysis at increasing concentrations of Ca\(^{2+}\) or Mg\(^{2+}\)-ions with this preparation resembled closely those previously reported for gill membranes of rainbow trout (Ma et al., 1974), American eels (Fenwick, 1976), roach (Shephard, 1981), and tilapia (our unpublished observations). The calculated $K_a$-values for Ca\(^{2+}\)- or Mg\(^{2+}\)-activation of ATP hydrolysis are similar to previously published values (Fenwick, 1979). The differences in $V_{max}$-values presented here and those in the earlier literature may be the result of the use of more highly purified membrane fractions in the present study and from differences in incubation temperatures.

**Characteristics of the Ca\(^{2+}\)-activated ATPase activities**

One of the results of this study we wish to emphasize is that the assay procedures previously employed for Ca\(^{2+}\)-activated ATPase activities in fish gills (among others) did not fulfil the requirements for the determination of transport Ca\(^{2+}\)-ATPases. Rather they yielded non-specific activities of Ca-ATP or Mg-ATP hydrolyzing enzymes. To support this contention we propose four major criticisms. (1) The affinity of the reported ATPase for Ca\(^{2+}\) was too low for an enzyme that must be stimulated by Ca\(^{2+}\) at intracellular Ca\(^{2+}\)-concentrations. (2) This Ca\(^{2+}\)-stimulated ATP hydrolysis, even measured at suboptimal pH (Fenwick, 1979), exceeds the Na\(^{+}/K\(^{-}\)-ATPase activity and, therefore, would indicate Ca\(^{2+}\)-transport rates that would surpass the Na\(^{+}\)-transport rates by several orders of magnitude. (3) No evidence was provided that ATP was the preferential substrate. (4) The pH-optima for the activities were reportedly in the alkaline trajectory (Ma et al., 1974; Fenwick, 1976) and were thus characteristic for alkaline phosphatase.

Because of these criticisms we conclude that the observed activation curves for Ca\(^{2+}\)- or Mg\(^{2+}\)-induced ATP hydrolysis represent saturation curves for complexes of ATP with either metal ion rather than Ca\(^{2+}\)- or Mg\(^{2+}\)-activation of ATP-hydrolyzing enzymes. Hydrolysis of ATP is strictly dependent on the presence of Ca\(^{2+}\) or Mg\(^{2+}\), suggesting that ATP alone is not (detectably) used as a substrate. Upon addition of Ca\(^{2+}\) or Mg\(^{2+}\) to ATP-containing media, these metal ions will be chelated by ATP (Walaas, 1958; Sapper et al., 1980). Although Mg\(^{2+}\) is chelated more strongly than Ca\(^{2+}\) by ATP, both interactions have the same modifying effect on the conformation of the adenosine-phosphate-ester and thus allow effective binding of the phosphate group to the active site of enzymes. In this context it should be mentioned that Na\(^{+}/K\(^{-}\)-ATPase (Bonting and Caravaggio, 1963) as well as the typical transport Ca\(^{2+}\)-ATPases of rat intestine (Ghijsen et al., 1980) are dependent on Mg\(^{2+}\)-ATP although they may be inhibited by Ca\(^{2+}\)-ATP (Epstein and Whittam, 1966).

Maximum velocities are found at equimolar concentrations of Ca\(^{2+}\) or Mg\(^{2+}\) and ATP or ADP. However, when Ca\(^{2+}\) or Mg\(^{2+}\)-ion concentrations exceeded the ATP-concentration by 2.5 or 5.0 mM, ATP-hydrolysis was inhibited. This indicates that Ca-ATP and Mg-ATP hydrolysis is inhibited by high levels of free Ca\(^{2+}\) or Mg\(^{2+}\) respectively.

The possibility cannot be excluded that in our assay procedures, stimulation of free or complexed ATP hydrolysis occurs by micromolar concentrations of free Ca\(^{2+}\) or Mg\(^{2+}\). But if we assume that the presence of both Ca\(^{2+}\) and Mg\(^{2+}\) in the assay medium is a prerequisite for the determination of a transport Ca\(^{2+}\)-ATPase, it is clearly not possible to show such an enzyme with the assay procedures applied in this and many other studies. Additionally, we want to stress that free Ca\(^{2+}\)-ion concentrations of the assay media in the micromolar range cannot be obtained reliably unless appropriate buffering with EGTA or NTA is employed (Sharff, 1979, 1981; Ghijsen et al., 1980).

Moreover, when a surplus of ATP relative to Ca\(^{2+}\) is used, new substrate will constantly be produced in the assay medium as the free ATP will react with the reaction product Ca-ADP to produce Ca-ATP and ADP. When this Ca\(^{2+}\)-dependent substrate production occurs, the activation curve represents the effects of Ca\(^{2+}\)-defined substrate concentrations rather than the effects of Ca\(^{2+}\)-concentrations on ATP-hydrolytic activities. When ADP was substituted for ATP in this type of experiment, comparable results were obtained. No phosphate release occurred in the absence of Ca\(^{2+}\). The shape of the activation curve observed resembled the one for ATP and suggested that the hydrolysis of ADP is also dependent on the chelation of Ca\(^{2+}\).

As P-release was measured as an indication of substrate hydrolysis in all cases, no straightforward answer can be given as to whether these activities were the result of the hydrolysis of a single sub-
chelation of these metal ions by the substrates rather than a direct stimulation of enzymes by Ca$^{2+}$ or Mg$^{2+}$. But it cannot be excluded that the P$_i$ measured when Ca$\sim$ATP is the substrate, originates from a Ca$\sim$ATP, an ATP hydrolyzing activity (or both) after stimulation by micromolar concentrations of free Ca$^{2+}$ present in the reaction media. For the determination of such "high-affinity" Ca$^{2+}$-ATPases the assay media must contain Ca$^{2+}$-buffers to establish reliably micromolar concentrations of Ca$^{2+}$.

**Effects of various inhibitors on Ca$\sim$ATP and Mg$\sim$ATP hydrolysis**

As the previously reported pH-optima for Ca$^{2+}$-activated ATPase activities approximated a value of 8.0 (Ma et al., 1974; Fenwick, 1976) we deduced that most of the P$_i$-release was due to non-specific alkaline phosphatases and we therefore tested the effects of various inhibitors on Ca$\sim$ATP and Mg$\sim$ATP hydrolysis. l-Phenylalanine, theophylline and l-cysteine are reported to affect non-specific phosphatases with alkaline pH-optima. Chlorpromazine, phenothiazine and calmidazolium (R24571) are reported to act as calmodulin-antagonists in a concentration-dependent way and to inhibit calcium transport in rat enterocytes and human erythrocytes by inhibition of the high-affinity transport Ca$^{2+}$-ATPases (Ghijsen et al., 1982; Gietzen et al., 1981).

l-Phenylalanine (up to 10 mM) did not affect Ca$\sim$ATP or Mg$\sim$ATP hydrolysis under our standard conditions (pH 7.4). These results concur with the results of Ghosh and Fishman (1966), who similarly reported that phosphatase activity was not inhibited by l-phenylalanine at pH-values below 7.8. On the other hand, Ghijsen et al. (1980) did report significant l-phenylalanine-induced inhibition of alkaline phosphatase activity in rat enterocyte plasma membranes, at a pH of 7.4. This discrepancy may reflect the organ-specificity of l-phenylalanine suggested by Ghosh and Fishman (1966). Other explanations for this discrepancy are that the kind of substrate used was not appropriate to show the effects of the inhibitor, or the fact that membrane preparations were used instead of pure enzymes. Theophylline, a more potent inhibitor of alkaline phosphatase activities than l-phenylalanine, had maximal effects at a concentration of 1.25 mM on both Ca$\sim$ATP and Mg$\sim$ATP hydrolysis, but the Ca$\sim$ATP hydrolysis was inhibited to a greater extent than the Mg$\sim$ATP hydrolysis. This suggests that Ca$\sim$ATP was the preferred substrate for a gill phosphatase activity. However, both Ca$\sim$ATP and Mg$\sim$ATP can be hydrolyzed by theophylline-sensitive enzyme activities. Maximum inhibition produced by theophylline was 20% of the total hydrolytic activity indicating again heterogeneity of enzyme activity. Cysteine, an alkaline phosphatase inhibitor that acts by binding the intrinsic Zn$^{2+}$-ion gave up to 80% inhibition of both Ca$\sim$ATP and Mg$\sim$ATP hydrolysis. Calculated I$_{50}$ values, however, differed significantly for these substrates: I$_{50}$Ca$\sim$ATP: 5.0 mM, I$_{50}$Mg$\sim$ATP: 2.2 mM. Thus, the cysteine would seem to act by dissociation of the substrate-complexes rather than
directly via the enzymes. Therefore, these results do not allow the conclusion that the phosphate release is due to the presence of Zn$^{2+}$-containing enzymes.

The phenothiazines inhibited Mg$\sim$ATP and Ca$\sim$ATP hydrolysis to a different extent: maxima were only 6% for Ca$\sim$ATP and 15% for Mg$\sim$ATP. This finding suggests that a large quantity of non-specific phenothiazine insensitive phosphatase activity was present. But whether the effects of these inhibitors at high concentrations resulted from competition with calmodulins, which are abundantly present in these membrane preparations (unpublished observation) or resulted from an effect on membrane integrity, causing reduced hydrolytic activity (Van Belle, 1981), remains to be elucidated.

Tentatively, we conclude that at least a portion of the Ca$\sim$ATP and Mg$\sim$ATP hydrolytic activity is calmodulin dependent. This calmodulin-sensitive component preferentially hydrolyzes Mg$\sim$ATP. However, the calmodulin-antagonists attenuate Ca$^{2+}$-activated ATPase activity only to a small extent. The latter conclusion indicates that a major part of the presumptive Ca$^{2+}$-ATPase activity cannot be involved in active Ca$^{2+}$-transport.

In further studies on Ca$^{2+}$-stimulated phosphatases in eel gill plasma membranes we were able to discriminate between non-specific, Ca$^{2+}$-stimulated phosphatases and high-affinity Ca$^{2+}$-ATPase activity that may represent the calcium pump (data to be published separately). In fresh water adapted eels, both activities are correlated negatively with the environmental Ca$^{2+}$-concentration. Although the non-specific Ca$^{2+}$-stimulated phosphatase activity does not fulfil the requirements of a Ca$^{2+}$-transport ATPase, some relation of this activity with Ca$^{2+}$-transport phenomena seems to exist. Thus, more than one enzyme activity located in the plasma membrane may be involved in gill transepithelial Ca$^{2+}$-transport.
