A profile of The Clinical Course of Cognition and Comorbidity in Mild Cognitive Impairment and Dementia Study (The 4C study): two complementary longitudinal, clinical cohorts in the Netherlands

Weiqi Liao^{1†}, Renske E. G. Hamel^{2†}, Marcel G. M. Olde Rikkert³, Saskia M. Oosterveld¹, Pauline Aalten², Frans R. J. Verhey², Philip Scheltens⁴, Nicole Sistermans⁴, Yolande A. L. Pijnenburg⁴, Wiesje M. van der Flier⁵, Inez H. G. B. Ramakers² and René J. F. Melis^{1*}

Abstract

Background: Heterogeneous disease trajectories of mild cognitive impairment (MCI) and dementia are frequently encountered in clinical practice, but there is still insufficient knowledge to understand the reasons and mechanisms causing this heterogeneity. In addition to correlates of the disorder, patient characteristics such as their health status, social environment, comorbidities and frailty may contribute to variability in trajectories over time. The current paper outlines the study design and the study population of and provides an overview of the data collected in the *Clinical Course of Cognition and Comorbidity in Mild Cognitive Impairment (4C-MCI cohort, n = 315) and Dementia (4C-Dementia cohort, n = 331) Study*.

Methods: The two complementary longitudinal cohorts part of the 4C study began enrolment in March 2010. Participants were prospectively recruited from three collaborating Dutch Alzheimer Centers, with three annual follow-up assessments after baseline. Extensive neuropsychological assessments, and detailed profiling of comorbidities, health and frailty at each follow up were the key features of the 4C study. As such, the 4C study was designed to study if and how patients' comorbidities and frailty are associated with the course of MCI and dementia measured with a comprehensive and multidimensional set of outcomes including cognition, daily functioning, quality of life, behavioral disturbances, caregiver burden, institutionalization and death and whether the effects of medical health and frailty differ between MCI and dementia stages of cognitive disorders.

Conclusion: Sampled in a clinical setting, the 4C study complements population-based studies on neurodegenerative disorders in terms of the type of assessment (e.g. comorbidity, frailty, and functional status were repeatedly assessed). The 4C study complements available clinical cohorts of MCI and dementia patients, because the exclusion criteria were kept to a minimum, to obtain a sample that is representative for the average patient visiting a memory clinic.

Keywords: Mild Cognitive Impairment (MCI), Dementia, Disease progression, Cognition, Comorbidity, Frailty

Background

Dementia is a syndrome of impaired cognitive functioning that interferes with living independently. It is a global public health issue with numbers of people suffering from dementia estimated to increase from 46.8 million in 2015 to 74.7 million in 2030, and to 131.5 million in 2050 worldwide [1]. Mild cognitive impairment (MCI) is a state of impaired cognitive performance that does not significantly interfere with independent living and is a risk factor for developing dementia. Both in MCI and dementia, progression over time varies tremendously among patients. Some patients with MCI progress precipitately after the diagnosis, whereas a substantial proportion of patients does not develop dementia even after a prolonged period of up to 10 years [2]. In the stage of a clinically manifest dementia syndrome, studies have shown huge differences in rate of decline over time, even within a well-characterized cohort of persons with dementia of the Alzheimer type [3]. Understanding the causes leading to heterogeneous trajectories is essential for healthcare professionals to deliver personalized care and to maximally delay the progression of the condition. However, current knowledge cannot explain the phenotypical heterogeneity present in patients. Part of the heterogeneity in dementia presentation might be attributed to different etiologies, such as (the combination of) Alzheimer's or vascular pathology. To further increase our understanding of the observed heterogeneity, a theoretical framework has been developed that posits dementia as a multi-causal, complex and dynamic disorder with involvement of many body systems/organs at different levels, rather than a disease with a single pathology [4]. The majority of patients with MCI and dementia are aged and may experience different levels of frailty and suffer from a considerable number of comorbidities that may affect clinical phenotype [5–9]. How these patient characteristics influence the development and prognosis of the disorder is largely unknown. With the aim to evaluate the impact of comorbidity and frailty on the course of MCI and dementia, *the Clinical Course of Cognition and Comorbidity in Mild Cognitive Impairment and Dementia Study (4C study)* was conducted. The current paper outlines the study design, the study population and an overview of the data collected.

4C study research objectives

As part of the 4C study two complementary multicenter longitudinal cohorts were sampled in the Netherlands, with the following research objectives:

1. Explore heterogeneity in trajectories of progression in multiple outcomes, survival and institutionalization, as well as conversion rates (MCI to dementia and back and between different nosological subtypes) in persons with newly diagnosed MCI and dementia;
2. Investigate whether comorbidity (number and severity of chronic comorbidities and presence of certain comorbidities) and frailty influenced the course and outcome of MCI and dementia;
3. Investigate predictors of transitions (conversions, institutionalization, death) as well as compare outcome trajectories right before and after transitions.
4. Investigate predictors and outcome trajectories of persons who did not convert from MCI to dementia and who were not institutionalized
5. Develop prognostic rules for conversion and individual decline in cognition, behavior, and daily functioning, institutionalization and death.

These research objectives are studied both in the separate samples of MCI and dementia as well as in the combined sample to evaluate differences between these stages of increasingly severe cognitive decline.

Construction and content

Study design and participants

The MCI and Dementia cohort of the 4C study were similar in study design and implementation, but were conducted in different disease stages. Both cohorts aimed to enroll 300 participants at baseline, equally from the three participating centres Alzheimer Center of the VU University Medical Center Amsterdam, Alzheimer Centre Limburg of the Maastricht University Medical Center and Radboudumc Alzheimer Center, Radboud university medical center. The departments hosting the three memory clinics have a background in neurology (Amsterdam), old age psychiatry (Maastricht) and geriatric medicine (Nijmegen).

The study base of this cohort study were all persons referred to one of the three memory clinics by their primary care physician or referring medical specialist. The inclusion period ran from the March 2010 until May 2011. All consecutive referrals were prospectively evaluated for study eligibility during that period.

People with a new diagnosis of dementia made during this memory clinic visit were eligible for the Dementia cohort. Patients who had subjective cognitive decline or objective cognitive impairments based on neuropsychological test results, but did not fulfill the diagnostic criteria for dementia were eligible for the MCI cohort. The exact eligibility criteria for the 4C–MCI and the 4C–Dementia cohorts are shown in Table 1. As such the inclusion was broader than in most studies on MCI and dementia since comorbidities were allowed, thus resulting in a patient sample that was more representative for regular patient groups.

The clinician responsible for the care during the memory clinic visit asked whether patients would be willing to consider participation in the 4C study. If so, they were provided with written study information and a visit was scheduled with a research assistant to obtain written informed consent from the participant and an informant and to complete the baseline assessments. In order to be eligible, an informant had to be available and have contact with the participant for at least once a week. Almost all informants (about 90%) were either the participant's partner or offspring, often also serving in a caregiving role. Not all participants had an informant who provided care that qualified as informal caregiving. However, if such a person could be identified, this person was asked as the informant. As a rule the same informant participated across the follow ups. In a small number of cases exceptions were allowed to minimize missings.

Data collection

The participants were scheduled to have three annual follow-ups after the baseline measurement during visits at the memory clinic. Annual follow-ups had to be conducted within a 3 months' time frame around the dates of an annual schedule. The last assessment in the participants who last entered the study was conducted in August 2014. The flowcharts for both cohorts are shown in Figs. 1 and 2.

A multidisciplinary team consisting of physicians, neuropsychologists and research assistants collaborated in the standardized collection of the baseline and follow up data with the patient and the informant. As such, the multidisciplinary team (led by a consultant neurologist, psychiatrist or geriatrician respectively) responsible for the clinical care of the participant at the memory was also responsible for the research data collection. Data were collected on demographics, syndrome diagnosis, cognitive functioning, health conditions, functional abilities, neuropsychiatric symptoms, quality of life, and care resource use. An overview of the collected data per measurement, who was the source of the information and who collected the information is presented in Table 2. The assessor scored the reliability of the participant's answers.

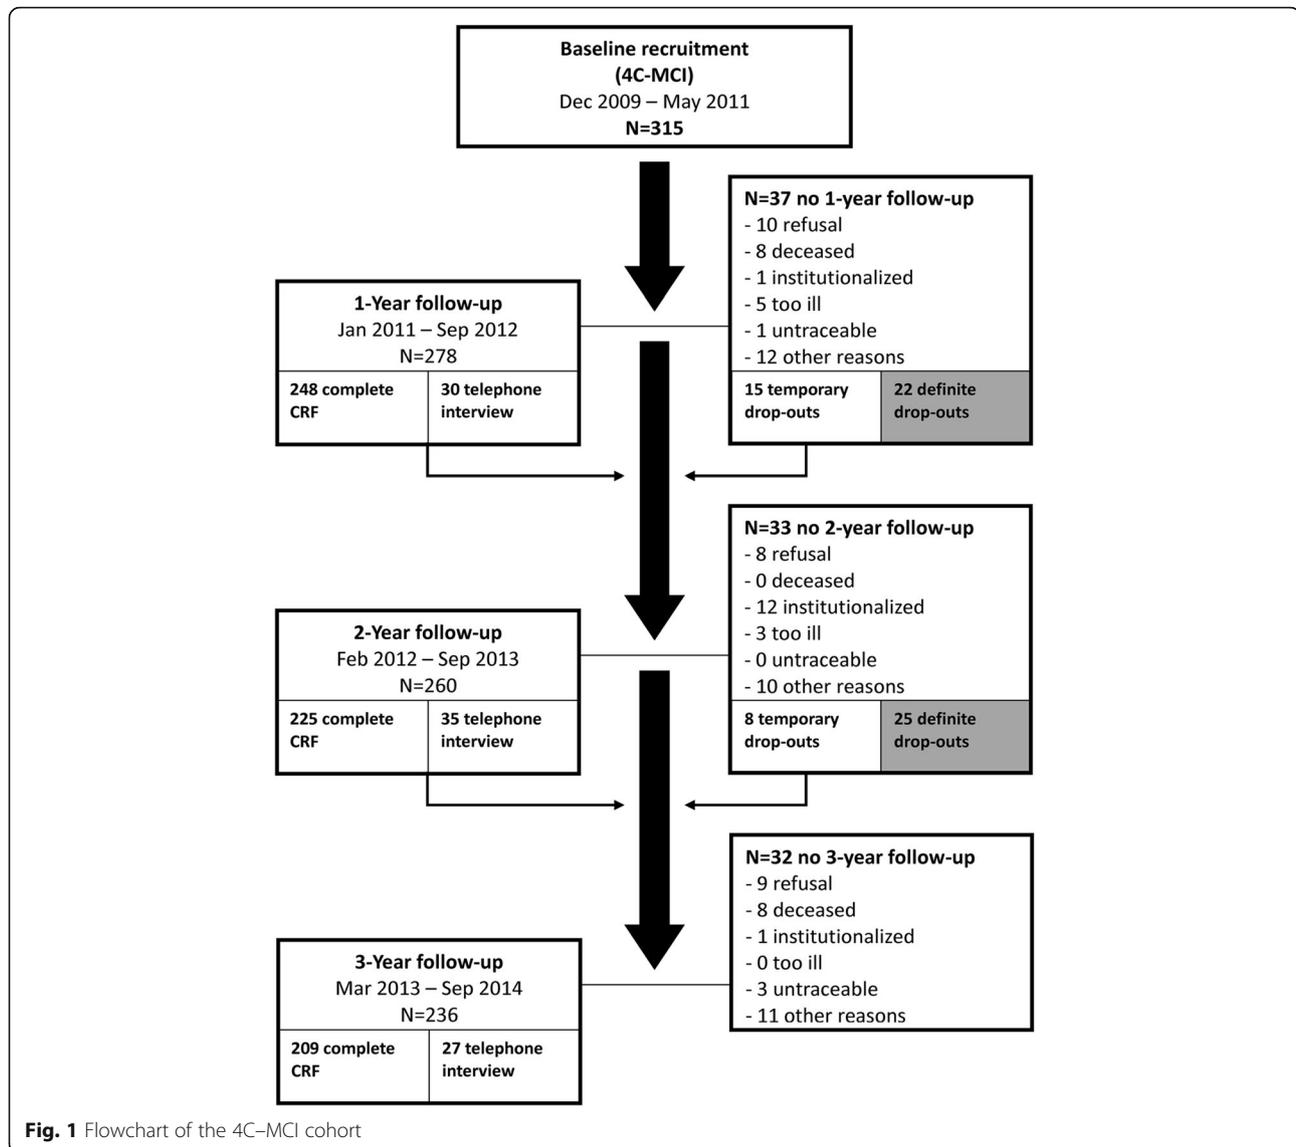

In order to minimize the dropout rate, home visits by a researcher trained as a psychologist were implemented for those participants who were willing to continue participation in the study but unable to visit the memory clinics. In case participants needed an institutionalization, they continued with the study. The possibility to do the follow up assessment during a home visit also facilitated this.

Syndrome diagnosis of MCI and dementia

Syndrome diagnoses were made at baseline and reviewed at every follow-up visit based on clinical

Table 1 Eligibility criteria for the 4C Study

Inclusion criteria	The 4C–MCI cohort	The 4C–Dementia cohort
• Cognitive performance	subjective cognitive complaints and/or objective cognitive impairments	objective cognitive impairments
• Fulfil the DSM-IV diagnostic criteria for dementia [12]	No	Yes
• Clinical Dementia Rating (CDR) Scale [34]	0–0.5	0.5–2
• Mini Metal State Examination (MMSE) score [35]	Not specified	≥10
• Age	≥ 55 years	Not specified
Exclusion criteria (similar for both cohorts)		
• The absence of a reliable informant (who has contact with the participant for at least once a week);		
• If the participant was expected unable to have at least one follow-up based on clinical judgment of the physician responsible for the care of the patient at the memory clinic;		
• The presence of other neurological disorders that could cause cognitive impairment or affect cognitive performance, such as Parkinson's Disease, Huntington's Disease, Normal Pressure Hydrocephalus (NPH), Korsakov's syndrome, and a medical history of brain tumour, encephalitis or epilepsy. However, participants suffering from other cerebrovascular or psychiatric disorders were included in the studies.		

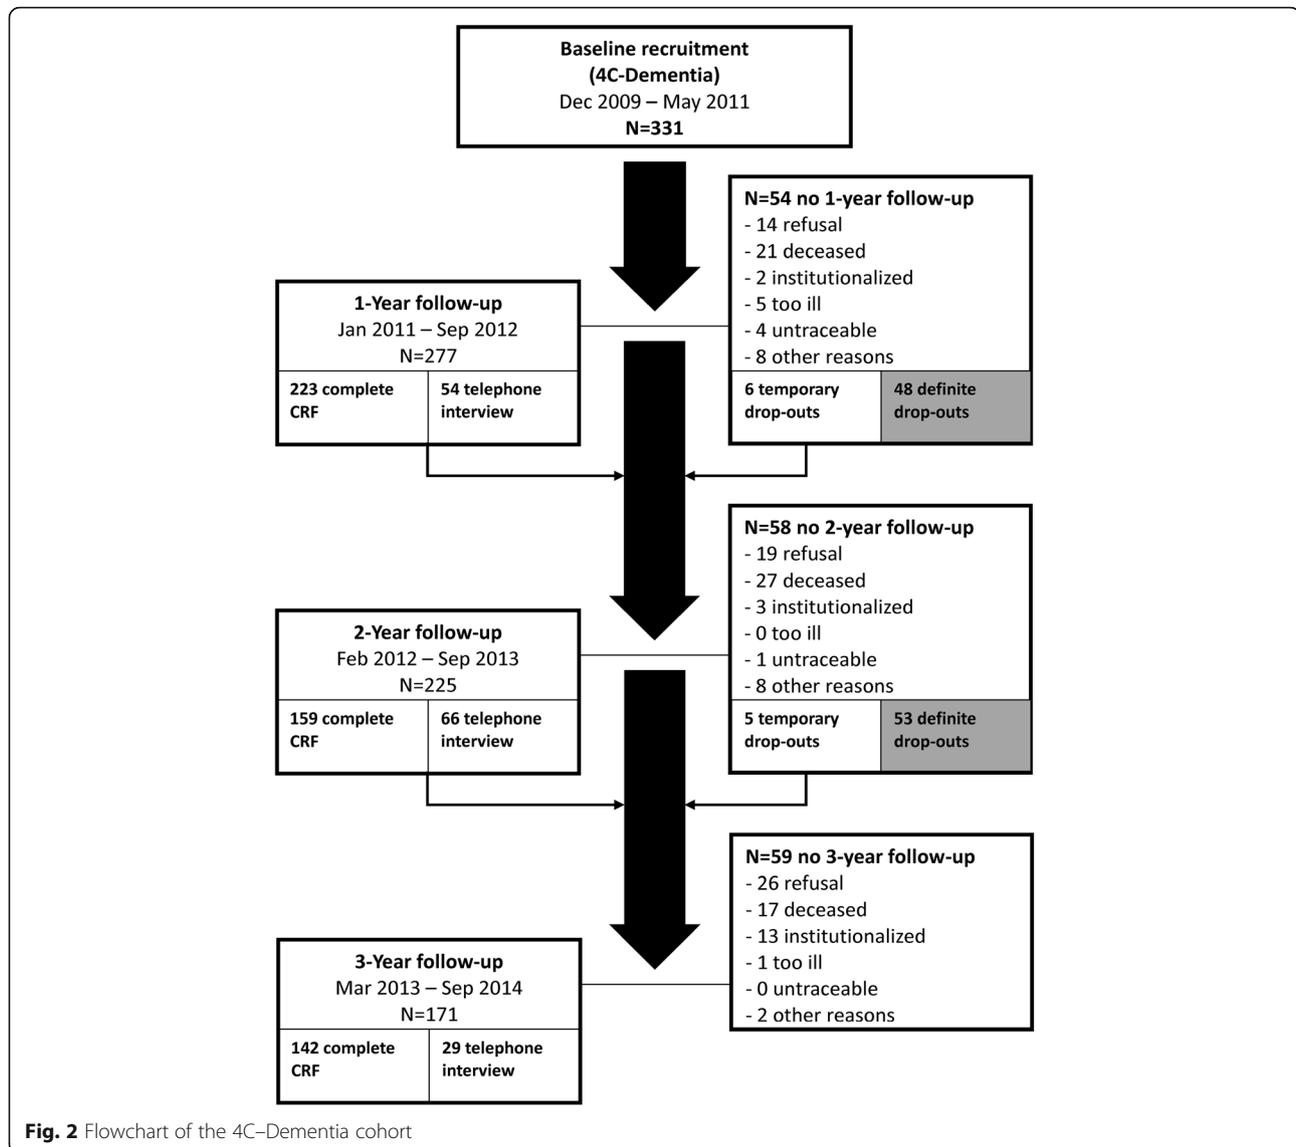

assessment by the physician and the multidisciplinary team. For the minority of cases in whom the follow up assessments were operationalized as a home visit, the diagnosis review was determined by a physician from the research data. The diagnosis of MCI was based on Petersen criteria [10] and was operationalized as a z-score lower than -1.5 SD (Dutch norm) on any of the cognitive tests (see below). Subjects with cognitive complaints without such a verified impairment on cognitive tests were categorized as subjective cognitive decline (SCD) [11]. The diagnosis of dementia was based on DSM-IV criteria [12]. Nosological dementia diagnoses were made according to standardized clinical criteria for AD (NINCDS-ADRDA criteria [13]), vascular dementia (NINDS-AIREN criteria [14]), frontotemporal dementia [15], and dementia with Lewy bodies [16].

Cognitive assessment

Data about the self-reported onset (gradual or sudden), course (stable, fluctuating or progressively deteriorated) and duration of the cognitive complaints were collected. In addition, patients were asked whether they had noticed a change in four cognitive functions (memory, concentration, mental capacity, and vitality) during the last year [17]. Change in each function was scored on a 7-point Likert scale ranging from -3 (very strong decline) to +3 (very strong improvement). If the participant was unable to answer by himself, the informant reported it based on daily contact and observation.

The neuropsychological assessment consisted of the same standardized battery of cognitive tests as used in the Dutch Parelsnoer Instituut (www.parelsnoer.org), covering the following domains: global cognition, episodic memory, implicit visual learning, working memory, word fluency,

information processing speed, attention, executive functioning and visual perception (Table 3) [17].

Further assessments and questionnaires

Height, weight, and, waist circumference, systolic and diastolic blood pressure of the participants were recorded. Smoking and drinking status, the type, quantity and frequency of tobacco and alcohol consumption were asked. The physician structurally reviewed the patient's personal medical history at baseline, and particularly queried extrapyramidal symptoms, gait disturbances, and family history. Newly diagnosed diseases were updated at every follow-up visit, also recording any taken medication and each hospitalization (Table 4).

The Cumulative Illness Rating Scale for Geriatrics (CIRS-G) was used to further quantitatively measure

disease burden and reflects the number and severity of the diseases [18]. Using CIRS-G, all diseases were classified into 14 organ systems: cardiac (heart only), vascular, hematologic, respiratory, ophthalmologic and otorhinolaryngologic, upper gastrointestinal, lower gastrointestinal, hepatic and pancreatic, renal, genitourinary, musculoskeletal and tegumental, neurologic, endocrine/metabolic and breast, and psychiatric. If a patient had multiple diseases in a single category, the most severe one was appraised. The severity of impairment was rated with a 0–4 grading scale from no problem to extremely severe problem (e.g. organ failure) resulting in a total score ranging from 0 to 56. The CIRS-G can be adapted as a measure of pure physical functioning in the 4C studies by excluding the psychiatric category, since this category includes cognition related comorbidities. The total score runs from 0 to 52.

Table 3 Standardized cognitive tests and the corresponding domains

Cognitive domain(s)	Neuropsychological tests
Global cognition	Mini Mental State Examination (MMSE) [35]
Episodic memory	15-Word Verbal Learning Test (VLT) immediate recall (5 trails), delayed recall and delayed recognition [36]
Implicit associative visual learning	Visual Association Test (VAT), short version [37]
Working memory	Digit Span subtest (forwards and backwards) of the Wechsler Adult Intelligence Test (3rd Edition) [38]
Verbal word fluency/semantic memory	60 s animal fluency [39]
Information processing speed	Letter Digit Substitution Test (LDST) [40]
Information processing speed, attention and executive functioning/response inhibition	Stroop Color Word Test (SCWT) [41]
Information processing speed, attention and executive functioning/concept shifting	Trail Making Test (TMT) parts A & B [42]
Visual perception	Visual Object and Space Perception battery (VOSP, Optional) Subtests of dot counting and incomplete letters [43]

Frailty was operationalized using the five physical criteria developed by Fried (2001) [19]. To that aim, grip strength (dominant hand, average of two measures) was measured using a Jamar® hand dynamometer and gait speed while walking at usual speed across 4.5 m (average of two measures). Unintentional weight loss and fatigue (two questions of Center for Epidemiologic Studies Depression Scale (CES-D)) were evaluated using questionnaires. Impaired physical activity was evaluated by

Table 4 Structural medical review of participant's health conditions

Body systems	Concerned diseases
Cardiovascular	angina, myocardial infarction, angioplasty/stent, coronary bypass surgery, carotid stenosis, hypertension, heart failure, others
Cerebrovascular	transient ischemic attack (TIA), cerebrovascular accidents (infarction, bleeding), reversible ischemic neurologic deficit (RIND), others
Endocrinal	diabetes mellitus, hypothyroidism, hyperthyroidism, obesity, others
Psychiatric	depression, psychosis, delirium, others
Somatic	chronic obstructive pulmonary disease (COPD), kidney problems, liver problems, others
Medications	the names, doses, frequencies and the indications of the medications
Hospitalization	the primary diagnosis, acute or routine medical care, the treating department, the total number of nights spent in the hospital

asking whether the participant yes or no exercised, performed household chores, did odd jobs around the house or gardened. If they did any of these, this item was scored as not impaired. If participants did not engage in any of these activities they were asked to rate the time per week engaged in biking or walking. Multiplying these estimates by 4 and 3.5 kcal/min respectively and summing them resulted in the estimated weekly energy expenditure related to biking and walking. If this estimate was below 393 or 280 kcal/week for men and women respectively, physical activity was scored as impaired. A frailty index based on accumulated deficits also was operationalized from the 4C data [20].

The Disability Assessment for Dementia (DAD) scale, measuring both basic and instrumental activities of daily living (ADL, IADL), was used to evaluate the severity of impairment in everyday functioning through a structured interview with the informant [21]. The participants' abilities to perform ten different (I)ADL activities in the 2 weeks prior to the assessment were rated. The final DAD score was converted to a percentage from 0 to 100, in which a higher percentage indicates a higher level of daily functioning.

The 4C study used the Geriatric Depression Scale (GDS-15) to assess the presence and severity of depressive symptoms in older persons [22]. The Neuropsychiatric Inventory (NPI) was used to characterize the psychopathology of the patient through a structured interview with the informant, assessing 12 common neuropsychiatric symptoms [23]. A screening question for each neuropsychiatric symptom was asked to confirm the presence of the symptom before rating the frequency (1–4, rarely–very often), severity (1–3, mild–severe), and burden (0–5, not at all–extremely) for the informant. The total NPI score ranged from 1 to 144.

The EQ-5D was used to measure health-related quality of life and results in a score of 0–100, where higher scores indicate better functioning [24]. The EQ-5D was rated by the patient and by the informant: for the situation of the patient and for the informant him-/herself.

Besides patient and disease related data, also data about the patient's care resource use was investigated by assessing the number of visits to the general practitioner, home care, day care, institutionalized care, hospital in- and out-patient, emergency care, other professionals, informal care, medical goods, and out-of-pocket expenditures using an informant questionnaire.

Refusal or withdrawal, minimum but essential data collected for research

The reasons for dropout were collected and categorized. The attrition is shown in the flowchart of Figs. 1 and 2. With their consent, the study investigators made efforts to collect minimal but essential study data through a

telephone interview when the participant (or informant) wanted to discontinue their full participation. Researchers asked about the course of cognitive symptoms, functional abilities in (I)ADLs (any help or assistance needed in certain activities), and global severity of dementia (CDR). If the participant had received a diagnosis of MCI or dementia from another physician, the syndrome diagnosis was documented. Despite the participant's refusal to participate in a particular follow-up assessment, some patients agreed to be approached at the next follow up and did return to fully participate in the studies, as shown in Figs. 1 and 2.

Adaptations of study protocol and implementation

Some changes to the original research protocol were made for better implementation and completion of the studies. Based on the experiences of baseline interview, an evaluation of the reliability of information provided by the participant and the informant was added to the follow up assessments.

As a default, the assessments were carried out in the memory clinics. However, for some participants, it was inconvenient to visit the memory clinic due to immobility or other physical conditions. Where possible, home visits (to the patient's house or nursing home) were implemented in the follow-ups and carried out by a well-trained researcher, to limit study attrition.

Utility and discussion

Results

In the MCI and dementia cohort, 315 and 331 participants were included respectively. Noticeably, more men than women were recruited in the MCI cohort (Table 5), consistently across the three centers, whereas more women were recruited in the Dementia cohort, except in Amsterdam. Participants in the MCI cohort were 5.2 years younger, and had better cognitive performance, functional abilities, physical condition and quality of life, but had higher depression scores on average than those in the Dementia cohort at baseline (Table 6).

Of 315 participants in the 4C-MCI cohort, 90 (29%) had subjective cognitive decline and 151 (48%) had amnesic MCI. Of 331 participants in the 4C dementia cohort, 216 (65%) had probable or possible AD. The majority of the participants experienced a progressive cognitive decline in the phase before the baseline diagnosis, namely 68% in the MCI cohort, and 89% in the Dementia cohort, starting at about 3–3.5 years on average before entering in either cohort. Episodic memory was the most severely impaired cognitive domain among MCI patients, whereas among dementia patients, multiple cognitive functions were severely impaired, especially executive functioning, attention and information processing speed.

Table 5 Baseline demographic characteristics of the participants in the 4C Study

N (%), unless stated differently	4C-MCI cohort (n = 315)	4C-Dementia cohort (n = 331)
Age at baseline (years, mean \pm SD)	69.7 \pm 8.5	74.9 \pm 10.2
Female sex	111 (35)	182 (55)
Caucasian	311 (99)	326 (98)
Education		
Low (lower than middle school)	126 (40.0)	142 (44.1)

Single, divorced	29 (9.2)	35 (10.6)
Living situation		
Alone, independently	59 (18.7)	100 (30.5)
With partner and/or children	242 (76.8)	205 (62.5)
Institutionalized living	9 (2.9)	21 (6.4)
Others	5 (1.6)	2 (0.6)
Informant's relation with the participant		
Partner	224 (71.1)	179 (54.4)
Offspring	60 (19.5)	115 (35.0)
Sibling	7 (2.2)	10 (3.0)
Other relative or acquaintance	23 (7.3)	25 (7.6)

By quantitative measures of disease burden (CIRS-G), vascular diseases were the most frequent and most severe comorbid category in both cohorts. The total CIRS-G score leaving out the category of psychiatric illness was higher in the dementia than in the MCI cohort. For the AD patients in the dementia cohort, it was found that comorbidities were associated with cognitive performance; frailty was associated with functional abilities at baseline [25]. Comparing older and younger persons with dementia contrasting persons from the 4c Dementia cohort data with persons from the NeedYD cohort [26], showed that younger persons had less comorbidity and may more often have neurological comorbidities than older persons with dementia [27]. Further studies into the relationship of cognitive decline with comorbidity and frailty are underway. In addition to the objectives described earlier, these will focus on determinants of health-related quality of life and gait speed and grip strength as predictors of cognitive decline in the MCI cohort.

The most prevalent neuropsychiatric symptoms reported by the informants in the MCI cohort were irritability (51%, average score 5.4 out of 12 in NPI), apathy/indifference (44%, 5.3) and depression/dysphoria (41%, 4.7). These neuropsychiatric symptoms were also most common in the dementia cohort, with different rankings: apathy/indifference (51%, 6.5), depression/dysphoria (38%, 5.3), irritability (36%, 5.3). When it occurred, agitation and aggression (mean 3.3; SD 1.13) was most burdening for informants in the MCI cohort. This was also the most burdening symptom in the Dementia cohort (3.0 \pm 1.3).

After 3 follow-ups, 23 subjects (23/90, 26%) classified as SCD at baseline were reclassified as MCI, 23 subjects (23/225, 10%) with MCI reverted to SCD, and 74 subjects (10 subjects with SCD at baseline and 64 subjects with MCI at baseline) progressed to different types of dementia (Table 7). The annual incidence of MCI subjects progressing to dementia was 11% (32/278) in the first 12 months, 7% (18/260) between 12 and 24 months and 10% (24/236) between 24 and 36 months of follow up. In the dementia cohort, 91 patients (27%) received at least one different (nosological) diagnosis of dementia during the follow-ups. Of these 91, three participants were re-diagnosed as MCI, and one participant went from dementia to MCI (12 m) and via again dementia (24 m) to SCD (36 m). Thus, in 4 (1.2%) of 331 participants the dementia diagnosis was reconsidered. 16 patients (5%) in the MCI cohort and 75 (23%) in the Dementia cohort died during 36 months of follow-up. Studies to develop and validate prognostic rules from these data are underway.

What are the main strengths and weakness?

One of the main questions for the 4C study was whether the interaction with health status would influence the natural disease course of cognitive disorders, and contribute to the heterogeneity of clinical outcomes. Thus, including participants with comorbidity in the study and getting reliable diagnoses of comorbidities were essential strengths of our studies, leading to more representative patient groups. Prospectively sampling diverse participants with natural disease courses from various routine clinical settings (neurology, geriatrics and old age psychiatry departments) who were representative for the MCI and dementia patients regularly seen in memory clinics was another strength. Finally, cognitive functioning is a central feature of MCI and dementia. In the 4C study, in addition to global measures of cognition, a series of standardized and validated neuropsychological tests were available to detail how different cognitive domains changed and to explore the effect of comorbidities on cognitive functioning in different domains over time. While some longitudinal studies

^a3 (1% of 315) participants in the 4C MCI cohort with MCI could not be classified as amnesic versus non-amnesic MCI due to missing 15-Word Verbal Learning Test scores

^bDespite the application of the Petersen criteria for definition of MCI, mean cognitive scores on the different domains may be above -1.5 SD of the Dutch norm scores, because people with SCD were included in the 4C MCI cohort, but do not satisfy the MCI criteria, also MCI patients were not required to score below -1.5 SD on all domains assessed

^cthe range of the CIRS-G is 0–52 rather than 0–56, as the psychiatric domain was left out of the scale to create a measure of purely physical comorbidity

focusing on risk factor discovery for dementia onset continue to follow persons who develop MCI and/or dementia, dedicated follow up studies are indispensable to understand the more advanced stages of cognitive decline. As such, the 4C study complements other population-based and clinical MCI and dementia follow up cohorts. In general, population-based (e.g. [28] or [6]) and clinical samples of MCI and dementia (e.g. [29] or [30]) are complementary in that the population-based

Table 7 The incidence of MCI subjects progressing to dementia within the study duration

Study time line	Number of subjects		%
	MCI conversion to dementia	In the cohort	
1 year follow-up	32	278	11.5
2 year follow-up	18	260	6.9
3 year follow-up	24	236	10.1
Total	74	315	23.4

studies have the advantage of being systematically sampled from well characterized base populations, whereas the clinical samples are able to add more detail in terms of frequency and type/comprehensiveness of assessment. To maximize the combined value of these data [31], initiatives such as IALSA [32] and COSMIC [33] help to identify datasets as well as provide methodologies in their combined analyses.

Discerning typical disease trajectories based on long-term observation and developing prediction models for disease progression would be beneficial for patient care. However, for frontotemporal dementia, dementia with lewy bodies or other types of dementia, due to limited cases, more effort should be made to include more patients in future studies to increase the power or combining the current samples with other studies.

Attrition was the biggest challenge for the 4C study, although it is inevitable due to the nature of the disease and the aged population (see Figs. 1 and 2). In the MCI cohort, 225 of 315 (71%) participants completed all three follow ups (209; 66%) or completed follow ups until the endpoint of death (16; 5%). In the Dementia cohort, 207 of 331 (63%) participants completed all three follow ups (142; 43%) or completed follow ups until the endpoint of death (65; 20%). Another 10 participants died during the 36 months of follow up, but dropped out of the study for one of the other reasons.

Conclusions

Sampled in a clinical setting, the 4C study database complements population-based studies on neurodegenerative disorders in terms of the type of assessment (e.g. comorbidity, frailty, and functional status were repeatedly assessed). The 4C study complements available databases of clinical cohorts of MCI and dementia patients, because the exclusion criteria were kept to a minimum, to obtain a sample that is representative for the average patient visiting a memory clinic. Cognition, functional abilities, resource use and quality of life were the key outcome domains and their longitudinal changes and dynamic relations will be further explored, also related to endpoints such as death and institutionalization.

(I)ADLs: (Instrumental) activities of daily living; 4C Study: The Clinical Course of Cognition and Comorbidity in Mild Cognitive Impairment and Dementia Study; AD: Alzheimer's disease; CDR: Clinical Dementia Rating scale; CIRS-G: Cumulative Illness Rating Scale for Geriatrics; DAD: Disability Assessment for Dementia; EQ5D: EuroQoL-5D; GDS-15: Geriatric Depression Scale-15; MCI: Mild cognitive impairment; MMSE: MiniMental State Examination; N.A.: Not applicable; NPI: Neuropsychiatric Inventory; SCD: Subjective cognitive decline; SCWT: Stroop Color Word Test (3 subtasks); SD: Standard deviation; TMT: Trail Making Test (part A & B); VAS: Visual Analogue Scale; VLT: 15-Word Verbal Learning Test

Acknowledgements

The authors would like to thank all the participants and their informants, research assistants and clinical staffs for their continuous contribution for the

4C studies over years. The authors thank Nico Rozendaal for his help with the design of the database and data management of the 4C cohorts. Research of the VUmc Alzheimer center is part of the neurodegeneration research program of the Neuroscience Campus Amsterdam.

Funding

The 4C studies were supported by Alzheimer Nederland and the VSB foundation. Grant numbers: 2008 3494 (4C-MCI), 2008 3495 (4C-Dementia). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. The VUmc Alzheimer Center is supported by Stichting VUmc fonds.

Availability of data and materials

The 4C research group actively encourages and welcomes external collaborations. Data are available for researchers with a specific research question. Interested and potential collaborators are invited to contact the study coordinators (Dr. René Melis Rene.Melis@radboudumc.nl or Dr. Inez Ramakers i.ramakers@maastrichtuniversity.nl).

Authors' contributions

WL and REH contributed equally to the conception of this manuscript and drafted the manuscript and performed the statistical analyses under the direct supervision of IHR and RJM. All other authors participated in the interpretation of the data and revised drafts of the manuscript for important intellectual content. The data collection was performed and coordinated by REH, NS and SMO under the direct supervision of IHR and RJM. PA, RJM, FRV, and MGO conceived the research questions, designed the study and wrote the study proposal. PS and WMF revised the study proposal for important intellectual content. All authors read and approved the final manuscript.

Competing interests

The authors declare that they have no competing interests.

Consent for publication

Not applicable.

Ethics approval and consent to participate

The ethical committees of the institutes Alzheimer Centre Limburg of the Maastricht University Medical Center, and Radboudumc Alzheimer Center, Radboud university medical center participating in this study approved the study. The 4C-MCI cohort was assessed by the METC azM/UM (NL25214.068.09/MEC 09-3-038) and the 4C-Dementia cohort by the CMO Arnhem-Nijmegen (CMO 0529, registratienummer 2010/046) respectively. The clinician responsible for the care during the memory clinic visit asked whether patients would be willing to consider participation in the 4C study. If so, they were provided with written study information and a visit was scheduled with a research assistant to obtain written informed consent from the participant and an informant and to complete the baseline assessments.
