SF3B1 and EIF1AX mutations occur in primary leptomeningeal melanocytic neoplasms; yet another similarity to uveal melanomas

Heidi V. N. Küsters-Vandevelde, David Creytens, Adriana C. H. van Engen-van Grunsven, Marcel Jeunink, Veronique Winnepenninckx, Patricia J. T. A. Groenen, Benno Küsters, Pieter Wesseling, Willeke A. M. Blok and Clemens F. M. Prinsen

Abstract

Introduction: Like uveal melanomas, primary leptomeningeal melanocytic neoplasms (LMNs) frequently carry GNAQ and GNA11 mutations. However, it is currently unknown whether these LMNs harbor mutations in BAP1, SF3B1 and/or EIF1AX like uveal melanomas as well. In this study, we used Sanger sequencing for the detection of mutations in SF3B1 (hotspots in exon 14 and 15) and EIF1AX (exon 1 and 2 and flanking intronic regions) in a series of 24 primary LMNs. Additionally, BAP1 immunohistochemistry was used as a surrogate marker for the detection of inactivating mutations in the BAP1 gene.

Results: Mutations in either SF3B1 or EIF1AX were identified in 8 out of 24 primary LMNs (33%). The presence of these mutations was mutually exclusive and occurred in primary LMNs of different malignancy grades (melanocytomas, intermediate-grade melanocytic tumors, melanomas). Complete absence of nuclear BAP1 staining as is typically seen in BAP1-mutated tumors was not observed.

Conclusions: Our finding that an SF3B1 or EIF1AX mutation is present in a substantial subset of primary LMNs underscores that these tumors genetically resemble uveal melanomas and are different from cutaneous melanoma at the genetic level. This information may not only aid in the differential diagnosis of primary versus metastatic melanocytic tumor in/around the central nervous system, but also in the identification of more promising therapeutic approaches targeting the molecular pathways involved in the oncogenesis of LMNs. As none of the primary LMNs in our series showed complete loss of nuclear BAP1 protein, it is unlikely that BAP1 mutations are frequent in these tumors but the role of this gene warrants further investigation.

Keywords: Leptomeningeal melanocytic neoplasms, Melanocytoma, Melanoma, Central nervous system, Neurocutaneous melanocytosis, BAP1, SF3B1, EIF1AX

Introduction

Primary leptomeningeal melanocytic neoplasms (LMNs) are infrequent tumors, forming a spectrum ranging from benign or low-grade malignant melanocytomas to frankly malignant melanomas [1]. These tumors share molecular features with uveal melanomas (UMs). In contrast to cutaneous melanomas (CMs), both LMNs and UMNs frequently carry mutations in the G protein encoding genes GNAQ and GNA11, whereas mutations in BRAF and in the TERT promoter are infrequent [2–8]. This situation reflects the heterogeneous molecular background of different groups of melanoma and has important implications for targeted therapy.

In the past years, inactivating mutations in the tumor suppressor gene BAP1 (BRCA-associated protein 1) were shown to be implicated in UM [9, 10]. The BAP1 gene is located on chromosome 3p21.1 and encodes a nuclear
ubiquitinase involved in epigenetic modulation of chromatin [11]. Somatic BAP1 mutations are predominantly present in UMs with monosomy 3 (~85%), the latter being a strong predictor for metastatic disease [9, 10, 12]. In this setting BAP1 functions as a tumor suppressor gene, with loss of one copy of chromosome 3 and mutation in the other BAP1 allele representing the two hits causing inactivation of this gene. Indeed, in UMs with disomy 3 (and a good prognosis), mutations in BAP1 are rare [6, 9, 10]. A small proportion of patients with UM (~2–3%) harbor a germline mutation in BAP1 [13]. These patients suffer from the BAP1 hereditary cancer syndrome and have an increased risk of developing cutaneous melanocytic tumors as well as a spectrum of non-melanocytic neoplasms including mesothelioma, renal cell carcinoma, meningeoma, and adenocarcinoma of the lung [14, 15]. Very recently, it was suggested that primary leptomeningeal melanoma is part of this cancer predisposition syndrome as well [16].

Furthermore, recurrent hotspot mutations in the SF3B1 gene (mainly at codon 625) and mutations of the EIF1AX gene (spread over exon 1 and 2) were recently reported in UMs, especially in tumors with disomy 3 (up to 30 and 50% of disomy 3 tumors, respectively) [17–19]. These mutations in UMs appeared to be largely mutually exclusively with BAP1 mutations, while in CMs these mutations were found to be very infrequent (~1%) [20].

It is currently unknown whether somatic mutations in BAP1, SF3B1 and EIF1AX also characterize primary LMNs. Using Sanger sequencing, we searched for mutations in hotspot regions of SF3B1 (exon 14 and 15) and exon 1 and 2 and flanking intronic regions of EIF1AX in a series of 24 primary LMNs. Additionally, we performed immunohistochemistry for the detection of BAP1 protein loss as a surrogate marker for identification of inactivating BAP1 mutations.

**Materials and methods**

**Patients and histopathology**

Formalin fixed and paraffin embedded (FFPE) tissue samples of twenty-four primary LMNs were obtained through the Dutch nationwide histopathology and cytopathology data network and archive (PALGA) [21]. Histology was revised by HK; WHO 2007 criteria were used for classification into melanocytoma, intermediate-grade melanocytic tumor and melanoma [1]. Information on mutation status of GNAQ, GNA11, BRAF, NRAS and chromosome 3 status of cases #1–7, #10, #13–18, and #22–24 has been published previously [2, 22, 23]. The study was approved by the local ethics committees of the Canisius Wilhelmina Hospital (ref.nr. LTC/TT/013–2015) and Radboud University (CMO, ref.nr/Dossiernummer: 2015–1692).

**DNA extraction**

Representative regions of about five 4-µm-thick FFPE sections with an estimated tumor cell percentage of at least 70% were manually dissected and used for DNA extraction. After heating in ATL buffer, the tissue sections were incubated in proteinase K for one hour; followed by subsequent purification of the DNA according to the manufacturer (QIAamp DNA Mini Kit, QIAGEN GmbH, Germany). After DNA purification, possible melanin contamination was removed by using an inhibitor removal kit (OneStep PCR Inhibitor Removal Kit, Zymo Research). The DNA sample concentration was assessed spectrophotometrically (Varian Cary 50 spectrophotometer, Agilent Technologies). The integrity of the isolated DNA was tested by means of a multiplex ladder PCR [24].

**BAP1 immunohistochemistry**

Immunohistochemistry was performed on 4-µm-thick FFPE sections using an automated immunostainer (Benchmark XT, Ventana Medical Systems, Tucson, AZ, USA) according to the manufacturer’s instructions. Sections were immunostained with a primary monoclonal antibody against BAP1 (clone C4, 1:100 dilution, Santa Cruz Biotechnology, Dallas, TX, USA) using 3,3-diaminobenzidine (DAB) as chromogen. Selected cases that showed a staining result that was difficult to interpret including strongly pigmented tumors (patients #1–8, #12–16, #22–24) were manually stained (clone C4, 1:50 dilution, Immunologic, Duiven, the Netherlands) according to the manufacturer’s instructions. The VECTOR NovaRED Peroxidase (HRP) Substrate Kit was used for visualization (Vector Laboratories, USA, Catalogue Number SK-4800). Nuclei of endothelial and lymphocytic cells in the slides served as positive internal control for BAP1 protein expression. The staining results were scored independently by three pathologists (HK, DC, WB). The percentage of positive tumor cell nuclei was scored only in areas with positive internal controls.

**Mutation analysis**

Sanger sequencing was used for analysis of mutations in hotspot areas of SF3B1 including codon 625 and codon 700 as well as for mutations in exon 1 and 2 and flanking intronic regions of EIF1AX. Primers are listed in Table 1. Normal tissue to exclude germline mutations was not available.

All primers contained a M13 forward or M13 reverse consensus sequence for sequencing. PCR amplification was performed in a total volume of 25 µl, containing 20 ng DNA, PCR Reaction Buffer with 20 mM MgCl2 (Roche), 200 µM of each deoxynucleotide triphosphate, 10 pmol of each primer and 2 units of FastStart Taq DNA polymerase (Roche). DNA amplification was performed in a Biometra T-Professional thermocycler (Westburg). The PCR was started with 5 min. at 95 °C
and followed with 40 cycles of denaturation 30 s at 95 °C,
annealing at 60 °C for 45 s and extension at 72 °C for 30 s,
followed by a final extension at 72 °C for 10 min. and
cooling down for 5 min. at 22 °C. All PCR products were
purified with ExoSAP-IT (Affymetrix). Two μl of the PCR
product was used for the sequence reaction on an ABI
PRISM 3500XL DNA analyzer (Applied Biosystems). Both
strands were sequenced using the M13 primers.

Information on BAP1 mutation status was available for
three patients (#20, #23, #24) (obtained by Sanger sequenc-
ing as previously described) while the chromosome 3 sta-
tus was in part obtained from a previous MLPA study [22,
25]. For all cases, the mutation status of GNAQ and
GNA11 (codons 209 and 183), BRAF (codon 600) and
NRAS (codons 12, 13 and 61) was available, part of this in-
formation has been published previously [2, 22, 23].

Results

Patients and histology

Main patient characteristics are summarized in Table 2.
The study group consisted of thirteen melanocytomas,
seven intermediate-grade melanocytic tumors and four
primary leptomeningeal melanomas. A subset of the tu-
mors was strongly pigmented.

All patients were adults, the age at operation ranging
from 27–69 years. None of the patients had clinical evi-
dence of primary melanoma outside the CNS. One pa-
tient was known with a large congenital melanocytic
nevus in the buttocks in the context of neurocutaneous
melanocytosis (patient #21). Two of the patients in this
series developed liver metastases, both after an initial histo-
logical diagnosis of intermediate-grade melanocytic tumor
(patients #19 and #20). One melanoma patient developed
distant metastases to bones and lungs (patient #23).

BAP1 immunohistochemistry

BAP1 immunohistochemistry was available in 20 out of
24 cases. For three cases there was no FFPE material left
for immunohistochemistry (patients #9–11), while in
one patient the tumor showed intense pigmentation,
preventing reliable interpretation of staining results (pa-
tient #6). Only nuclear staining was considered as posi-
tive, although cytoplasmic staining was found in a
substantial subset of tumors as well. In two melanocyto-
mas (patients #1 and #4), a mosaic pattern with alternating
positive and negative (areas of) nuclear staining was
present, the vast majority (about 80 %) of these nuclei
being positive (Fig. 1a, b). All other cases showed mod-
erate to strong nuclear staining in 90 % or more of nu-
clei. Complete absence of nuclear BAP1 staining as is
typically seen in BAP1-mutated tumors was not ob-
erved (Figs. 1, 2 and 3).

Mutation analysis

We detected a total of three mutations in SF3B1 (13 %),
including two hotspot mutations at codon 625 (R625C
and R625H) and one mutation affecting codon 634
(V634I) (Table 2). Mutations in codon 700 of SF3B1 were
detected. In the cosmic database the V634I mutation
in SF3B1 (c.1900G > A (p.(Val634Ile))) has not been re-
ported in cancer before (http://cancer.sanger.ac.uk/cos
mic). This mutation was present in a GNAQ-mutated
melanocytoma of a 27-year-old male patient who developed
leptomeningeal seeding shortly after initial presentation
(patient #4) (Fig. 1a, b, e).

One case with mutation in codon 625 of SF3B1
(c.1873C > T (p. (Arg625Cys))) concerned an intermediate-
grade melanocytic tumor showing aggressive behavior
with leptomeningeal seeding (patient #18). A concomitant
GNA11 mutation was present in this tumor while immu-
nohistochemistry showed intact nuclear BAP1 expression
(Fig. 1c, d, f).

The other mutation in codon 625 of SF3B1
(c.1874G > A (p. (Arg625His))) was present in a CNS
melanoma of a 31-year-old woman (patient #21). Since
birth this patient was known with a large congenital mela-
ocytic nevus on the buttocks for which multiple excisions
had been performed, confirming melanocytic nevus with-
out malignant transformation. At the age of 29, she de-
veloped an intracranial tumor in the left frontal region with
diffuse leptomeningeal extension. Biopsy showed melan-
oma in a background of diffuse melanocytosis, consistent
with the diagnosis of primary melanoma of the CNS occur-
rming in the context of neurocutaneous melanocytosis. This
was supported by the presence of an NRAS mutation in
both the CNS melanoma and in a more recent biopsy of
the melanocytic nevus (c.182A > G (p. (Gln61Arg))). In con-
trast, the SF3B1 mutation (c.1874G > A (p. (Arg625His)))
was present in the CNS melanoma but not in the mela-
ocytic nevus. Immunohistochemically, intact BAP1 protein
expression was found in the tumor cell nuclei of this
melanoma (Fig. 2).

A point mutation in E1F1AX was detected in five of
the primary LMNs in this series (21 %), each leading to

an amino acid substitution (at codons 3, 4, 9 or 10). These mutations occurred in tumors diagnosed as melanocytomas, intermediate-grade tumors, and melanomas (Fig. 3). In addition, one point mutation was detected in the Kozak consensus sequence of exon 1 (c.1–4C > T) which may have an influence on the start of translation (patient #1). *EIF1AX* mutations were mutually exclusive with *SF3B1* mutations and generally co-occurred with *GNAQ* or *GNA11* mutations (Table 2).

**Discussion**

In this study we investigated whether primary LMNs share genetic alterations with UMs in addition to *GNAQ* and *GNA11* mutations. Recently, a role for *BAP1* in primary melanoma of the CNS was suggested based on the identification of a *BAP1* germline mutation in a patient with primary CNS melanoma with monosomy 3 and a family history of UM and meningioma [16]. In our study, we chose for *BAP1* immunohistochemistry as a surrogate marker for the identification of an underlying inactivating *BAP1* mutation as it offers an economical and faster alternative to sequence analysis of all 17 exons of *BAP1* [12, 26, 27]. Typically, complete loss of nuclear *BAP1* expression is found in *BAP1*-mutated UMs [12, 26–28]. None of the samples in our series showed such complete loss of nuclear *BAP1* staining, suggesting absence of underlying *BAP1* mutations. In three cases (including the single patient

with monosomy 3 in the LMN and the patient with liver metastases but disomy 3 in the LMN), BAP1 mutation status was available through Sanger sequencing analyses and confirmed absence of mutations. However, our study has some limitations. In some cases, BAP1 mutations may still have been missed as BAP1 immunohistochemistry was reported to have a sensitivity of ~88% [12]. Also, very rarely, heterogeneous (‘mosaic’) BAP1 nuclear immunostaining has been described in UM cases with a BAP1 mutation showing loss of nuclear staining in only 20% of nuclei [12]. In our series, two cases showed nuclear BAP1 staining in about 80% of tumor cells and an underlying BAP1 mutation can thus not completely be ruled out. Furthermore, as BAP1 is mainly implicated in metastatic UM with monosomy 3, there might be a selection bias in our patient group as it mainly concerns (relatively) low-grade tumors with disomy for chromosome 3. A larger number of primary LMNs with monosomy 3 should thus be investigated to further explore the role of BAP1 in these neoplasms. This is also important for therapeutic reasons as epigenetic modulators such as histone deacetylase (HDAC) inhibitors were shown to reverse the biochemical effects of BAP1 mutations in UM cells by inducing growth arrest and differentiation. Clinical trials are now evaluating HDAC inhibitors as a therapeutic option in UM patients [13, 29].

Recurrent mutations in the SF3B1 gene have been detected in several types of cancer such as UMs, breast...
and pancreatic carcinoma, and hematological diseases like CLL and MDS [18, 30–33]. These mutations affect hotspot codons, the hotspot being associated with cancer type. For example, codon 700 mutations are frequently present in CLL and MDS, while in UMs codon 625 is much more frequently involved [18, 34]. Especially in low-grade UMs with disomy for chromosome 3, heterozygous mutations in SF3B1 are present in 10 to 30 % of UM [6, 17–19]. The fact that in UMs these SF3B1 mutations are almost mutually exclusive with BAP1 mutations suggests different pathways in the oncogenesis and/or malignant progression of these neoplasms. SF3B1 encodes subunit 1 of splicing factor 3b, which is a component of the spliceosome that participates in splicing of pre-mRNA. It was shown that SF3B1 mutations are associated with differential alternative splicing of several protein encoding genes in UMs [19]. Moreover, SF3B1 mutant cell lines were found to be sensitive to the SF3b complex inhibitor spliceostatin A, suggesting a new therapeutic target in tumors carrying this mutation [32]. Up to now, it was unknown whether SF3B1 mutations also occur in primary LMNs. In our series, in three out of 24 cases (13 %) an SF3B1 mutation affecting codon 625 or 634 was detected, this is at the lower end of the range of the frequency of SF3B1 mutations reported in UMs (10–30 %) and in contrast to the very low frequency reported for CMs (~1 %) [6, 17–20]. As far as could be assessed, all three

LMNs showing an SF3B1 mutation were tumors with disomy for chromosome 3. Furthermore, like in UMs, in two cases the SF3B1 mutation co-occurred with a GNAQ or GNA11 mutation, while in a third case (with neurocutaneous melanocytosis) an NRAS mutation was present. The GNAQ, GNA11 and NRAS genes are now thought to play a role in the initiation of tumorigenesis, while mutation in SF3B1 (or BAP1) would then occur in a later phase of the oncogenic process [18]. The co-occurrence of an NRAS and an SF3B1 mutation in the CNS melanoma of the neurocutaneous melanocytosis patient in our study is interesting in this respect as the SF3B1 mutation was absent in the congenital melanocytic nevus of this patient. Patients with neurocutaneous melanocytosis have a large and/or multiple congenital melanocytic nevi of the skin in association with a primary LMN [1]. Instead of GNAQ or GNA11 mutations, these patients frequently demonstrate identical NRAS mutations in both the congenital melanocytic nevus and in the LMN [35, 36]. This is thought to be the result of an NRAS-mutated clone of melanocyte precursors migrating to skin and CNS early in embryogenesis [37]. The observation that the SF3B1 mutation was not present in the melanocytic nevus of this patient suggests that it indeed plays a role later on in tumorigenesis. In addition, all three mutations in SF3B1 in our study were found in tumors which clinically showed aggressive behavior. However, the number of patients and the follow-up in our study are too limited to allow for firm conclusions about a prognostic role of SF3B1 in this setting. Of note, in one of the three patients the SF3B1 mutation (c.1900G > A (p.(Val634Ile))) was present in a neoplasm diagnosed as melanocytoma, suggesting that SF3B1 mutations are not necessarily associated with worrisome histology.

Several recent studies have reported mutations in EIF1AX in different cancer types, including melanoma and thyroid and ovarian cancer [17, 38, 39]. In UMs, heterozygous mutations in exon 1 and 2 of EIF1AX have reported to occur especially in tumors with disomy for chromosome 3 (up to 48 % of these tumors) [17]. Mutations may occur in different loci of these exons and lead to amino acid substitutions or short deletions. Rarely splice site mutations have been reported [6, 10, 17]. EIF1AX encodes the eukaryotic translation initiation factor 1A (eIF1A), which is involved in initiation phase of translation of eukaryotic cells by stabilizing the formation of the functional ribosome around the AUG start codon. The exact role of EIF1AX mutations in tumorigenesis is currently not well understood but it has been suggested that mutations in EIF1AX could diminish the rate of bulk translation [17, 40]. In our series of primary LMNs we found a relatively high frequency of EIF1AX missense mutations (21 %) which is in the range reported for UM (19–48 %) [6, 17]. In contrast, EIF1AX mutations are very rare in CM (5/231, ~2 %) [20]. As in UMs, as far as could be assessed in our series, these mutations occurred in primary LMNs with disomy for chromosome 3 and were mutually exclusive with SF3B1 mutations, but co-occurred with GNAQ or GNA11 mutations. In addition (and like SF3B1 mutations), the EIF1AX mutations in our cases occurred both in melanocytomas as well as melanomas, suggesting that they are not necessarily associated with worrisome histology, but the prognostic implications of these mutations remain to be elucidated. Finally, the EIF1AX and SF3B1 mutations in LMNs occurred in hotspot regions of these genes, and in UMs such mutations were shown to be somatic in origin [17, 18]. However, as non-neoplastic tissue of the patients with LMNs was not available for further testing, strictly speaking we cannot rule out the possibility that in some of these cases it concerned a germline mutation.

Conclusions
We report for the first time that a substantial subset of LMNs carries a mutation in SF3B1 or EIF1AX. Like in UMs, SF3B1 or EIF1AX mutations are mutually exclusive and generally co-occur with either a GNAQ or GNA11 mutation (SF3B1 occasionally with NRAS mutation), suggesting that SF3B1 and EIF1AX mutations occur later on in the tumorigenesis. Our findings may offer novel therapeutic strategies for especially patients with SF3B1-mutated LMNs. The role of BAP1 in the pathogenesis of primary LMNs is less clear, immunohistochemistry suggests that BAP1 mutation is infrequent in tumors with disomy for chromosome 3. However, more detailed analysis is needed for further elucidation of the role of BAP1 in the oncogenesis of primary LMNs. Demonstration of BAP1 mutations in primary LMNs would potentially have therapeutic relevance as well, as epigenetic modulators are now being evaluated in patients with BAP1-mutant UMs. All in all, this study thus underscores the genetic resemblance of primary LMNs and UMs and provides some additional clues for the diagnosis of and therapeutic interference with these tumors.
