ABSTRACT
We use radial velocities from spectra of giants obtained with the WIYN telescope, coupled with existing chemical abundance measurements of Na and O for the same stars, to probe the presence of kinematic differences among the multiple populations of the globular cluster (GC) M13. To characterize the kinematics of various chemical subsamples, we introduce a method using Bayesian inference along with a Markov chain Monte Carlo algorithm to fit a six-parameter kinematic model (including rotation) to these subsamples. We find that the so-called extreme population (Na-enhanced and extremely O-depleted) exhibits faster rotation around the centre of the cluster than the other cluster stars, in particular, when compared with the dominant ‘intermediate’ population (moderately Na-enhanced and O-depleted). The most likely difference between the rotational amplitude of this extreme population and that of the intermediate population is found to be ∼4 km s$^{-1}$, with a 98.4 per cent probability that the rotational amplitude of the extreme population is larger than that of the intermediate population. We argue that the observed difference in rotational amplitudes, obtained when splitting subsamples according to their chemistry, is not a product of the long-term dynamical evolution of the cluster, but more likely a surviving feature imprinted early in the formation history of this GC and its multiple populations. We also find an agreement (within uncertainties) in the inferred position angle of the rotation axis of the different subpopulations considered. We discuss the constraints that these results may place on various formation scenarios.

1 INTRODUCTION
All well-studied Galactic globular clusters (GCs) exhibit star-to-star abundance variations with enhancement in N, Na, and Al, and depletion in C and O (and occasionally depletion in Mg; e.g. Gratton, Carretta & Bragaglia 2012). The study of Carretta et al. (2009) has revealed that typically 60–70 per cent of the cluster stars show light-element abundance variations that are not usually found in field stars, although recent work by Milone et al. (2016) showed that the fractions of cluster stars with a chemical composition differing from halo stars are less uniform (ranging from ∼33 per cent to ∼92 per cent) than those from the sample of Carretta et al. (2009).† Understanding the origin of the light-element abundance spreads among GCs is one of the great unsolved problems in the study of stellar populations, and its solution potentially encodes crucial information that would reveal how GCs form.

† Note that the observed fraction of enriched stars depends on the radial distribution of the subpopulations and the region of the cluster sampled, and may thus differ from the true ‘global’ fraction of enriched stars. Milone et al. (2016) measure the ‘local’ fraction in the central regions of the clusters from Hubble Space Telescope (HST) photometry, while Carretta et al. (2009) infer it from spectroscopic studies sampling more external regions.

Two popular scenarios for the formation of multiple populations invoke multiple star formation episodes, where later generations form out of gas polluted by the ejecta of an earlier generation of stars. These scenarios typically adopt fast-rotating massive stars (e.g. Decressin et al. 2007) or asymptotic giant branch (AGB; e.g. D’Ercole et al. 2008) stars as the stellar candidates responsible for the chemical anomalies observed ubiquitously in GCs. In both these scenarios, the mass of stellar ejecta available to form later generations is insufficient to account for the large observed fractions of enriched stars. To overcome this issue, these scenarios either adopt a non-standard initial mass function for the different generations (e.g. Decressin et al. 2007) and/or predict that GCs were 10–100 times more massive at birth (e.g. D’Ercole et al. 2008).

This last implication is, however, in conflict with observations of the number ratio of GC and field stars in nearby dwarf galaxies (Fornax, WLM, and IKN), which suggests that GCs in these systems could not have been more than about five times more massive initially (Larsen, Strader & Brodie 2012; Larsen et al. 2014). In addition to the two sources of enriched material mentioned above, supermassive stars with \( M \sim 10^4 \, M_\odot \) have also been considered as polluters to explain the detailed abundance patterns observed in GCs (Denissenkov & Hartwick 2014; Denissenkov et al. 2015). Bastian et al. (2013) also proposed a scenario that does not involve multiple generations of stars, and in which the enriched material is released by massive interacting binaries (de Mink et al. 2009) and accreted on to the circumstellar discs of low-mass pre-main-sequence stars from the same stellar generation (although see Wijnen et al. 2016, which highlights important limitations regarding the efficiency of such an accretion process). For a more detailed review of the different formation scenarios for multiple populations developed so far, in particular, with respect to their shortcomings in simultaneously reproducing the observed abundance patterns of Na, O, and He in different GCs, we refer to Bastian (2015), Bastian, Cabrera-Ziri & Salaris (2015), and Renzini et al. (2015). In short, none of the scenarios proposed so far provides a complete and satisfying explanation to the presence of multiple populations in GCs.

Understanding the formation and evolution of GCs and their multiple populations requires theoretical and observational efforts. From the observational perspective, the presence of light-element abundance variations has been probed by using low- (e.g. Smith et al. 1996; Harbeck, Smith & Grebel 2003; Smolinski et al. 2011) or high-resolution spectroscopy (e.g. Kraft 1994; Gratton, Sneden & Carretta 2004; Carretta et al. 2009), and with photometry using narrow-band filters covering molecular bands sensitive to the abundances of C, N, and O abundances (e.g. Lardo et al. 2011; Piotto et al. 2015; Massari et al. 2016), where the light-element abundance spreads show up as split or broad sequences in the colour–magnitude diagrams (CMDs).

Additional insights have emerged by studying large samples of stars covering a wide spatial range in several GCs. For instance, Lardo et al. (2011) found a difference in the radial distributions (from about the half-light radius and beyond) of the different populations identified using Sloan \( u-g \) photometry in a number of GCs (M2, M3, M5, M13, M15, M53, and M92). In their study, the presumably N-enriched stars were found to be more centrally concentrated. Previous low-resolution spectroscopy studies have also found that the N-rich population is more centrally concentrated in the metal-rich GC 47 Tuc (e.g. Briley 1997). This finding was confirmed by Milone et al. (2012) using HST photometry and by Cordero et al. (2014) using high-resolution spectroscopy. A spatial separation among the multiple populations in GCs could have been imprinted during the early stages of GC formation. For instance, in the scenario proposed by D’Ercole et al. (2008), a second generation forms in the central regions of a cluster. Furthermore, Vesperini et al. (2013) studied the long-term dynamical evolution of a multiple generations scenario with initial spatial segregation. Their \( N \)-body simulations indicate that the multiple populations do not fully mix spatially until a GC has lost \( \sim 60\text{–}70 \) percent of its initial mass due to two-body relaxation (see also Hénault-Brunet et al. 2015; Miholics, Webb & Sills 2015). In this framework, the multiple populations of dynamically less evolved GCs, such as 47 Tuc, are not completely mixed and still exhibit an imprint of their initial distributions, whereas GCs that have lost a large fraction of their mass would be fully mixed spatially (e.g. NGC 6362 – Dalessandro et al. 2014; Miholics et al. 2015; M71 – Cordero et al. 2015a).

It is, however, worth noting that the trend of a more centrally concentrated enriched population may not be universal. Using HST/WFC3 photometry, Larsen et al. (2015) found that the giants with a normal composition are more centrally concentrated than the enriched giants in the inner parts of M15 (i.e. within the half-light radius). A similar reversed trend with respect to what was found in previous studies was also reported by Lim et al. (2016), who found the CN-weak stars to be more centrally concentrated compared to the CN-strong stars in the GCs NGC 362 and NGC 6723, although their samples (based on ground-based narrow-band photometry) are incomplete in the central regions of the clusters. Larsen et al. (2015) showed that to explain their observed radial distributions in M15 in terms of dynamical mass segregation, giants with a normal composition would need to be \( \sim 0.25 \, M_\odot \) more massive than their enriched counterparts. If this mass difference was due to a different initial helium composition for the different subpopulations, it would imply an extreme He enhancement for the enriched stars (\( Y \sim 0.40 \)), which is not compatible with the modest He enhancement deduced from the CMD of M15 (see Larsen et al. 2015, and discussions therein). Whether the spatial distribution trend observed in the central regions of M15 then reflects initial conditions (Larsen et al. 2015), or to what extent other factors – like a difference in the binary fraction of different chemical populations (see the paragraph below) or unaccounted observational systematic effects affecting the inferred radial distributions – could play a role, however, remains an open question (see e.g. Hénault-Brunet 2015). It will be interesting to compare future HST studies quantifying the spatial distribution of multiple populations in the inner parts of GCs with the behaviour reported in the above-mentioned studies.

Another piece of the puzzle comes from studies of binary star populations in GCs. Using \( N \)-body simulations to explore a scenario in which a second generation formed more centrally concentrated, Hong et al. (2015) predicted a higher binary disruption rate for ‘second-generation’ (Na-enriched) stars compared to ‘first-generation’ (Na-normal; ‘field-like’) stars. The first attempt to distinguish differences between binary fractions among multiple populations was done by D’Orazi et al. (2010), who found a...
lower binary fraction among Na-enriched stars by searching for Ba-enhanced giant stars in 15 GCs and radial velocity variations in NGC 6121. In the absence of multiepoch radial velocity measurements, Ba-enhanced stars allow us to trace the incidence of binaries assuming that the enrichment in Ba comes from s-process polluted material transferred from a former AGB binary companion. This assumption can be verified by modelling the s-process abundance pattern of Ba-enhanced stars with AGB yields. For instance, Cordero et al. (2015b) confirmed from the analysis of many s-process elements that the abundance pattern of an Na-normal s-process enhanced star in 47 Tuc is consistent with enrichment by mass transfer from a 1.3-M_⊙ AGB companion. Clearly, s-process polluted stars that are/were part of a binary system can provide insights into multiple populations and binary evolution, but because these stars are extremely rare in GCs, their use for testing GC formation models is limited. A systematic and effective search for differences in binary fractions between Na-normal and Na-enriched stars was performed by Lucatello et al. (2015) on a sample of 10 GCs. Their radial velocity campaign suggested that binary stars are more abundant among the Na-normal stars, which is consistent with the prediction by Hong et al. (2015) that the binaries of the Na-enriched population would be more efficiently destroyed if they were born in a denser environment (i.e. as part of a more centrally concentrated population). Given the lower mass at a given age of helium-enriched stars, binaries with enriched stars would also be easier to unbind (at the same encounter rate) than binaries with more massive ‘helium-normal’ stars, but the effect is expected to be small (Lucatello et al. 2015).

Besides chemical anomalies and intriguing spatial properties, the multiple populations of galactic GCs also display hints of kinematic differences in the outer regions of clusters (around the half-light radius and beyond). In a pioneering study of 20 GCs, Bellazzini et al. (2012) found a slightly lower line-of-sight velocity dispersion in the Na-enhanced groups of three GCs (NGC 6388, NGC 6441, and NGC 2808) compared with stars with a normal Na abundance. Furthermore, the Na-normal groups of three GCs in the Bellazzini et al. (2012) sample (NGC 2808, NGC 6171, and NGC 7078) seem to exhibit larger rotational amplitudes by a few km s\(^{-1}\) compared with Na-enhanced stars, although the differences reported were based on small samples and the statistical significance of these differences was not reported. Similarly, proper motion and radial-velocity studies suggest that the enriched population of 47 Tuc may have a lower velocity dispersion (Richer et al. 2013; Kucinskas, Dobrovolskas & Bonifacio 2014). Also in 47 Tuc, Richer et al. (2013) found that the presumably He-enriched stars (bluer main-sequence stars) have a more radially anisotropic velocity distribution (in the plane of the sky) based on HST proper motions in a field located around 2 half-light radii from the centre of the cluster. A similar signature was reported by Bellini et al. (2015) in NGC 2808, also based on HST proper motions, where stars between ∼1.5 and 2 half-light radii and coinciding with the presumably He-enhanced populations show a more radially biased velocity distribution than the populations corresponding to normal non-enriched stars.

Connecting the kinematic and chemical properties of multiple populations in GCs offers a new approach for understanding how they formed. In particular, in the outer regions of clusters, where the relaxation time-scale is longer and mixing is less important, we may expect to see imprints of the initial conditions and formation process of multiple populations. The simulations of Bekki (2010, 2011), Mastrobuono-Battisti & Perets (2013, 2016), and Hénault-Brunet et al. (2015) have studied the synergy between the kinematic, spatial/morphological, and chemical properties of the multiple populations in GCs. In particular, Hénault-Brunet et al. (2015) explored what type of kinematic signatures would survive the long-term dynamical evolution of old GCs and may allow to distinguish different formation scenarios. Based on these results, it is worth emphasizing that the kinematic differences reported so far between multiple populations in some GCs are not unique signatures of a specific formation scenario. The observational evidence collected in the outer parts of clusters is generally consistent with an enriched population forming more centrally concentrated, which is predicted in all the scenarios proposed to date. If two-body relaxation has not completely erased spatial and kinematic differences between subpopulations, the population that is more centrally concentrated is indeed expected to be dynamically cooler (i.e. lower velocity dispersion) and to have developed a more radially biased velocity distribution as it diffuses outwards. As pointed out by Hénault-Brunet et al. (2015), a difference in the rotational amplitude of subpopulations is a potential signature that would provide further insight and possibly unique constraints to distinguish between formation scenarios, because the initial orbital configuration of normal and enriched stars implied by different scenarios can lead to opposite predictions for the sign of the difference in rotational amplitude.

In this work, we study the GC M13 (NGC 6205) from a chemodynamical perspective and perform the first systematic search for kinematic differences between its multiple chemical populations. This old (12.25 Gyr; VandenBerg et al. 2013) and moderately metal-poor ([Fe/H] ∼ −1.5; e.g. Johnson & Pilachowski 2012) GC exhibits relatively strong rotation (Lupton, Gunn & Griffin 1987; Cordero 2014; Fabricius et al. 2014), has an Na-enriched and O-depleted population that is more centrally concentrated (Lardo et al. 2011; Johnson & Pilachowski 2012), and has three chemical subpopulations as well (Johnson & Pilachowski 2012). The characteristics above, combined with the relatively large spectroscopic data set of Johnson & Pilachowski (2012) from which precise radial velocities and uncertainties can be extracted, along with the hint of a difference in the rotational amplitude of its multiple populations (Cordero 2014), make it an ideal target to perform such a study and introduce a robust statistical method to investigate the kinematics of multiple populations. We present the observations used in Section 2, our kinematic analysis of subpopulations in Section 3, a discussion of these results in Section 4, and summarize our findings in Section 5.

2 OBSERVATIONS

2.1 Data reduction and analysis

The spectra were acquired using the WIYN–Hydra fibre positioner (R ≈ 18,000) on 2011 May 19–20 (Johnson & Pilachowski 2012) and have a wavelength coverage ranging from 6050 to 6350 Å. The data-reduction process (see also Johnson & Pilachowski 2012) was accomplished with standard IRAF tasks, which included using the CCDPROC routine to trim and bias subtract the raw frames. The DOHYDRA routine was used to identify and trace the fibres, apply the flat-field correction, measure and apply the wavelength calibration, remove cosmic rays, extract individual fibres, and subtract the sky spectra. Several exposures for each star (ranging from 4 to 12 in our program) were taken to build high signal to noise ratio (S/N) spectra, which have been previously used to determine Fe, Na, and O abundances by Johnson & Pilachowski (2012). Individual exposures had S/N ranging from about 25 to 50. Relative radial velocities were measured on single exposures by cross-correlating the object spectrum with a smoothed synthetic spectrum of similar atmospheric parameters. The synthetic spectra used as a template are
interpolated models from the grids of Coelho et al. (2005). We used the cross-correlation task \texttt{FXCOR} in \textsc{iraf} to determine a cross-correlation profile, whose strongest peak represents the radial velocity of the star. \texttt{FXCOR} allows to interactively select wavelength regions that are clear of bad pixels and telluric features. For each star the strongest peak of the cross-correlation function was well fitted by a Gaussian. A quantitative estimate of the quality of the Gaussian fit, based on the Tonry–Davis R-value (Tonry & Davis 1979), is given by \texttt{FXCOR} in addition to the velocity measurement and its uncertainty. The R-value corresponds to the ratio of the strongest cross-correlation peak height to the average height of unselected peaks. As a rule of thumb, velocities with an R-value \geq 5 are regarded as reliable. In our sample, the R-values were always greater than 12 (and typically 30), ensuring that the velocities included in our analysis are reliable. Heliocentric corrections were applied to the relative velocities obtained for each exposure using the \textsc{iraf} task \texttt{RVCORRECT}. Radial velocities determined from different exposures of the same star were found to be in agreement. Finally, an error-weighted average heliocentric velocity with its error was computed for each star. The weighted average heliocentric velocity of the whole sample is $-244.8 \pm 0.5\; \text{km s}^{-1}$ (standard deviation $6.1\; \text{km s}^{-1}$), which is in agreement with the systemic velocity of $-246.2\; \text{km s}^{-1}$ reported by Lupton et al. (1987) and with the mean heliocentric radial velocity of $-244.2\; \text{km s}^{-1}$ (standard deviation $7.1\; \text{km s}^{-1}$) taken from the catalogue of Harris (1996, 2010 edition). These are also in agreement with our Bayesian determination of the mean velocity of the full sample (see Section 3).

Table 1 presents the identifications from Ludendorf (1905) and Kadla (1994), coordinates, $V$ magnitudes, error-weighted average heliocentric radial velocities, radial velocity errors, chemical abundance ratios for Na and O from Johnson & Pilachowski (2012), and a chemical population classification (see the next section) for a sample of 113 giant stars.

### 2.2 Chemical classification

All the stars in our sample have proper motion membership probabilities higher than 70 per cent,\textsuperscript{3} radial velocities within $3\sigma$ from the cluster’s mean radial velocity, and uniform [Fe/H] ratios within the errors, ensuring membership to the cluster. To assess the possible field contamination rate in our sample, we used the Besançon Galaxy model (Robin et al. 2003) to create a synthetic CMD and velocity distribution along lines of sight near M13. This exercise returned a 0.05 per cent probability that a random field star would have a velocity, metallicity, surface gravity, and colour that are similar to those expected for M13 giants. Combined with our previous membership vetting using the Cudworth & Monet (1979) proper motions, the Besançon simulation suggests that field star contamination in our sample is negligible. M13 has an extended Na–O anticorrelation, as can be seen in Fig. 1. To distinguish its multiple populations, we separated the Na-normal population, i.e. stars with a halo-like chemical composition ([Na/Fe] $< 0$ and [O/Fe] $> 0$), from the Na-enriched stars. We refer to the Na-normal population as P1. The Na-enriched stars constitute the majority of the sample and...
span a wide range of [O/Fe] abundance ratios (~1.5 dex). The Na-enhanced stars follow a continuous distribution in the Na–O plane, which is likely a consequence of the spectroscopic errors (typically 0.15 dex in [Na/Fe] and [O/Fe] for the stars in our sample), challenging the identification of different chemical groups. To overcome this issue, we used a k-means clustering algorithm on the Na-enhanced stars to separate the O-depleted stars from the extremely O-depleted stars. The k-means algorithm is a simple unsupervised machine-learning algorithm that randomly assigns cluster centres to the data; the cluster centres are refined by determining the vector mean of the initial clusters in an iterative process until convergence, allowing the classification of the full data set. The cluster membership of each data point is determined by minimizing the distance to the final cluster centres. These two groups were named P2 (Na-enriched and O-depleted stars) and P3 (Na-enriched and extremely O-depleted stars). Note that two stars in our sample have only Na or O abundance measurements, but not both. In particular, star L1050 does not have an Na estimate; however, its O abundance allows to classify this star as either P1 or P2 population. Similarly, star L29 does not have an O abundance; thus, L29 can be classified as either P2 or P3.

3 KINEMATIC ANALYSIS

3.1 Method

We describe in this section a Bayesian method aimed at quantifying the kinematic properties of the multiple chemical populations in the GC M13. We use a discrete fitting technique to compare a simple kinematic model (including a radial dependence of the rotational amplitude and velocity dispersion of the cluster) with individual radial velocities. We apply this method to the chemical subsamples P1, P2, and P3 defined in the previous section, as well as to the sample as a whole (P1 + P2 + P3) and to a combination of the subsamples P1 and P2. Radial velocity maps of the three main samples discussed below (P2, P3, and P1 + P2 + P3) are as shown in Fig. 2. An indication of rotation can already be seen just by looking at these velocity maps and noticing the velocity gradient across the cluster.

According to the Bayes theorem, the posterior probability distribution of the model parameters $\Theta$, given the data $x$, is given by

$$p(\Theta|x) = \frac{p(x|\Theta)p(\Theta)}{p(x)},$$  

(1)

where $p(\Theta)$ is the prior probability distribution, $p(x|\Theta)$ is the likelihood function, and $p(x)$ is the evidence. In the context of the present analysis, the latter is a normalization factor, which we will simply neglect. In the cases considered here, the data $x$ is a set of $N$ stars with radial velocities $v_i$ (and uncertainties $\sigma_{v,i}$) and known on-sky coordinates.

The probability of the data, given the model parameters, i.e. the likelihood function, is expressed as

$$p(x|\Theta) = \prod_{i=1}^{N} \Lambda_i(x_i|\Theta),$$

(2)

which is the product of individual likelihood functions $\Lambda_i(x_i|\Theta)$ calculated for every star in the sample. The likelihood function for the radial velocity of individual stars depends on our assumption for the rotation curve of the cluster as well as its velocity dispersion profile. For the velocity dispersion profile, we assume the functional form of the Plummer (1911) model, defined by its central velocity dispersion $\sigma_0$ and its scale radius $a$:

$$\sigma^2(R) = \frac{\sigma_0^2}{\sqrt{1 + R^2/a^2}},$$

(3)

where $R$ is the projected distance from the centre of the cluster. For the family of projected Plummer (1911) models, $a$ is equal to the half-mass radius, which is equivalent to the half-light radius if the mass-to-light ratio is constant throughout the cluster. Note that this is not necessarily the case for GCs, which are typically mass segregated due to their collisional nature, as appears to be the case for M13 (e.g. Goldsbury, Heyl & Richer 2013). We stress that our goal here is not to perform a detailed and self-consistent dynamical analysis of M13 but to search for possible differences in the kinematics of chemical subpopulations. In this purely kinematic approach, we thus chose the Plummer model merely for its convenient, simple, yet flexible parametrization and analytic description of a system with a constant-density core. As we illustrate below, this parametrization...
provides a satisfying description of the observed velocity dispersion profile (and of the different chemical subsamples considered), given the size of our data set and the quality of the data (see Section 3.2).

For the rotation curve, we assume cylindrical rotation and adopt a functional form inspired by the outcome of violent relaxation (Lynden-Bell 1967; Gott 1973), and parametrized in the following way (e.g. Hénault-Brunet et al. 2012; Mackey et al. 2013):

\[ V_{\text{rot}} \sin i (X_{\text{PA}}) = \frac{2 A_{\text{rot}} X_{\text{PA}}}{R_{\text{peak}}^2 (1 + (X_{\text{PA}}/R_{\text{peak}})^2)}, \]

where \( V_{\text{rot}} \sin i \) is the rotational amplitude along the line of sight at a projected distance \( X_{\text{PA}} \) from the rotation axis and \( A_{\text{rot}} \) is the peak rotational amplitude (again along the line of sight) occurring at a projected distance \( R_{\text{peak}} \) from the centre. We define the position angle (PA, with respect to the centre of the cluster) as increasing anticlockwise in the plane of the sky from north (PA = 0°) towards east (PA = 90°). We adopt negative values of \( V_{\text{rot}} \sin i \) for PAs between \( PA_0 \) and \( PA_0 + 180° \), where \( PA_0 \) is the PA of the rotation axis in the plane of the sky. Given that the inclination of the rotation axis with respect to the line of sight is unknown, \( V_{\text{rot}} \sin i \) is a lower limit to the actual 3D rotational amplitude (\( V_{\text{rot}} \)). If the rotational axis was aligned with the line of sight, the rotation would be in the plane of the sky and we would obviously miss any rotational signature when using radial velocities. With solid-body rotation in the inner parts and a rotation curve peaking at intermediate radii (around the half-mass radius) followed by a decline, the functional form above conveniently captures the general behaviour seen in self-consistent equilibrium models of rotating stellar systems (e.g. Lagoute & Longaretti 1996; Varri & Bertin 2012) as well as in evolutionary models of rotating GCs (e.g. Kim et al. 2002; Fiestas, Spurzem & Kim 2006; Hong et al. 2013). As we show below, this parametrization also satisfactorily reproduces the observed rotation curve of the cluster (as well as the rotation curve of the different chemical subsamples considered) obtained from binning the radial velocity data (see Section 3.2).

To avoid projection effects due to the non-negligible angular diameter and distance from the equatorial plane of M13, we project the coordinates of each star on the plane of the sky along the line-of-sight vector through the cluster centre (e.g. van de Ven et al. 2006), and use those projected Cartesian coordinates for our kinematic analysis.4

Assuming a Gaussian distribution of velocities, the likelihood function for an individual star is then given by

\[ L_i(x_i | \Theta) = \frac{1}{\sqrt{2 \pi (\sigma_{\text{vel}}^2 + \sigma^2)}} \exp \left( -\frac{(v_i - v_0 - V_{\text{rot}} \sin i)^2}{2 (\sigma_{\text{vel}}^2 + \sigma^2)} \right), \]

where \( v_0 \) is the systemic radial velocity of the cluster, with the other variables defined as above. Because our likelihood function is based on the conditional probability of a radial velocity measurement, given the position of a star, our fitting procedure is not biased by the spatial sampling of the stars in our sample and subsamples: The kinematics are simply better constrained in regions of the cluster that are better sampled, and less well constrained in regions that are poorly sampled. Note that we do not include a contamination term in our likelihood function since potential non-members have already been excluded from our data set.

Given that some metal-poor red giants within \( -0.5–1.0 \) mag from the red giant branch tip are known to exhibit a velocity jitter at the level of \( \sim 1.5–2.0 \) kms\(^{-1}\) (Carney et al. 2003), we also consider an additional broadening term in the Gaussian likelihood function above, such that \( \sigma_{\text{vel}}^2 \rightarrow \sigma_{\text{vel}}^2 + (2 \text{ kms}^{-1})^2 \) for bright giants within \( 1 \) mag from the red giant branch tip of M13 (\( V = 12 \)). This, however, affects only a fraction of our sample, and we performed additional experiments by running the same analysis but without including this velocity jitter term, which revealed that neglecting this effect would not affect our results and conclusions.

The model parameters that we vary to find the best match to the data are \( \Theta = \{ v_0, A_{\text{rot}}, R_{\text{peak}}, PA_0, \sigma_{\text{vel}}, \alpha \} \). For those parameters, we adopt uninformative uniform priors over the following ranges: \(-280 < v_0 < -220 \) km\(\text{s}^{-1}\), \( 0 < A_{\text{rot}} < 14 \) km\(\text{s}^{-1}\), \( 0.5 < R_{\text{peak}} < 6 \) arcmin, \(-180° < PA_0 < 180°\), \( 0 < \sigma_{\text{vel}} < 14 \) km\(\text{s}^{-1}\), and \( 0.5 < \alpha < 6 \) arcmin. The boundaries were chosen to bracket a wide range of possible values for our data set. In particular, we expect \( R_{\text{peak}} \) and \( \alpha \) to be comparable (within a factor of a few) to the half-light radius of M13 (1.69 arcmin based on the 2010 version of the Harris catalogue; Harris 1996). Throughout the analysis, we keep the position of the centre of M13 fixed at \( \alpha = 16^h41^m41^s, \delta = +36^\circ27'40.7'' \) (J2000).

To explore the parameter space and efficiently sample the posterior probability distribution for the parameters above, we use EMCEE (Foreman-Mackey et al. 2013), a PYTHON implementation of the affine invariant Markov chain Monte Carlo (MCMC) ensemble sampler of Goodman & Weare (2010). We typically consider 500 walkers, and for each of these, 800 steps in parameter space. Convergence is generally obtained within a few hundred steps or less, and we consider a burn-in phase of 600 steps for all our fits to be on the safe side. We also checked that our results are robust against changes to the initial positions of the walkers.

The method described above presents clear advantages over the traditional method used for detecting/characterizing the rotation in GCs (Cote et al. 1995; Bellazzini et al. 2012). The latter consists of dividing the line-of-sight velocity data set in two halves by a line passing through the centre with a given PA, and computing the mean line-of-sight velocity for each subsample. The PA of the dividing line is varied and the difference between the mean velocities is plotted against PA, and then the pattern is fitted with a sine function. The PA for which the difference in mean velocities is maximized gives an estimate of the PA of the rotation axis, and the amplitude of the sine curve gives an indication of the mean rotational amplitude. It is, however, difficult to obtain reliable uncertainties from that method because the data points shaping this sine pattern are all correlated (the mean velocity difference for each data point is computed from the radial velocities of the whole sample). Our discrete method deals in a straightforward and reliable way with the uncertainties on all fitting parameters, it avoids loss of information from binning the data, and it has the advantage of treating the velocity dispersion and rotational components simultaneously when comparing kinematic models with the data.

### 3.2 Results

Table 2 lists, for the different subsamples considered and for the six free parameters of our analysis, the median value from the posterior probability distribution function (marginalized over all other parameters), with error bars indicating the interval enclosing the central
Rotation of multiple populations in M13

Table 2. Median and ±1σ uncertainties for the six free parameters of the kinematic analysis of different chemical subsamples.

Figure 3. Line-of-sight velocity dispersion profile as a function of projected distance from the centre of the cluster for the subsamples P1 + P2 + P3 (left-hand panels), and P2 and P3 (right-hand panels). The upper panels show the profiles obtained from binning the data, and the lower panels show the best fits as solid lines with shaded regions illustrating the 1σ uncertainty envelopes of the dispersion profiles. Note that the fits were performed on the discrete velocities, and the binned profiles are shown here only for illustration purposes.

68 per cent of the probability distribution. We also show in Figs A1–A5 of Appendix A the 2D projections of the posterior probability distribution on the planes determined by every pair of parameters. These figures also show histograms of the marginalized posterior probability distribution for each parameter of the kinematic model.

Figs 3 and 4 show a comparison of the line-of-sight velocity dispersion profiles of different subsamples (P1 + P2 + P3, P1, P2, P3). The binned dispersion profiles are obtained by assuming an equal number of stars in each bin (apart from the outermost bin in which any additional leftover stars are also included) and using the maximum likelihood estimator of Pryor & Meylan (1993) to compute the dispersion in each bin and its uncertainty. For the radius of each bin, we adopt the mean radius of all the stars in that bin, and for the error bar on the radius, we simply assume that they extend over the whole radius range spanned by the stars in a given bin. Recall that the fits were performed on the discrete radial velocity measurements, so these binned profiles are shown here only for illustration purposes. Best-fitting dispersion profiles inferred from our fitting procedure are shown in the bottom panels of Figs 3 and 4, with shaded regions showing 1σ envelopes. To obtain these 1σ envelopes, we first sampled 1000 sets of parameters from the post-burn-in phase of a given MCMC chain. From those, we then compute the associated line-of-sight velocity dispersion profile. Then, at a given radius, we find the 16 per cent and 84 per cent percentiles of the dispersion of all 1000 dispersion profiles, and repeat for different radii. The solid lines representing the best-fitting profiles represent the median of all the computed profiles at each radius.

Similarly, Figs 5 and 6 show a comparison of the rotation curves (mean line-of-sight velocity as a function of projected distance from the rotation axis) of different subsamples (P1 + P2 + P3, P1, P2, P3). The binned rotation curves were obtained by adopting the best-fitting PA for the rotation axis (Table 2), assuming an equal number of stars in each bin (apart from the outermost bins) and using the maximum-likelihood estimator of Pryor & Meylan (1993) to compute the mean line-of-sight velocity in each bin and its uncertainty. Again, note that the fits were performed on the discrete radial velocity measurements (taking into account uncertainties in the PA of the rotation axis), not on the binned rotation curves. The 1σ envelopes on the best-fitting rotation curves shown in the bottom panels of Figs 5 and 6 were...
obtained in an analogous way as described above for the dispersion profiles.

We first note from Table 2 that the mean velocity ($v_0$) of all the chemical subpopulations considered is consistent (within 1σ) with the mean velocity of the cluster as a whole. The line-of-sight velocity dispersions of the different chemical subsamples are also consistent with each other within 1σ, with only a slight hint of a larger dispersion for population P1 compared to population P2, and a larger dispersion for population P2 compared to population

Figure 4. Same as the right-hand panels of Fig. 3, but comparing the line-of-sight velocity dispersion profiles of the subsamples P1 and P2.

Figure 5. Mean line-of-sight velocity as a function of projected distance from the rotation axis (i.e. rotation curve) for the subsamples P1 + P2 + P3 (left-hand panels), and P2 and P3 (right-hand panels). The upper panels show the rotation curves obtained from binning the data, and the lower panels show the best fits as solid lines with shaded regions illustrating the 1σ uncertainty envelopes of the rotation curves. Note that the fits were performed on the discrete velocities, and the binned profiles are shown here only for illustration purposes.

Figure 6. Same as the right-hand panels of Fig. 5, but comparing the rotation curves of the subsamples P1 and P2.
P3, a trend that is in keeping with the more centrally concentrated distribution of population P3 reported by Johnson & Pilachowski (2012) (see e.g. Hénault-Brunet et al. 2015). The observed dispersion profiles decrease with increasing radius within the range of our data.

A clear rotation signature is found for the cluster as a whole, with an amplitude $A_{\text{rot}} = 2.7^{+0.9}_{-0.8} \text{ km s}^{-1}$. We emphasize again that the rotational amplitudes reported here are lower limits to the 3D rotational amplitudes because our data are sensitive only to the line-of-sight component of rotation, and the inclination of the rotation axis with respect to the line of sight is unknown for M13. Rotation is also obvious in population P3 ($A_{\text{rot}} = 5.6^{+1.7}_{-1.6} \text{ km s}^{-1}$), while a much weaker rotational signal is found for the dominant population P2 ($A_{\text{rot}} = 1.3^{+1.1}_{-0.9} \text{ km s}^{-1}$ but consistent with no rotation within $2\sigma$), suggesting that population P3 is driving the rotation signature found in the full sample. Unsurprisingly, with a small number of stars in the P1 subsample, the kinematics of the ‘normal’ population are poorly constrained, in particular, its rotational amplitude (weak rotation but also consistent with no rotation within $2\sigma$) and the PA of its putative rotation axis. For the cluster as a whole and all subsamples, the rotation curve is consistent with solid-body in the inner parts followed by a decline beyond $\sim 2-3$ arcmin, although the peak at intermediate radii is visible only in the binned rotation curve of the groups P1 + P2 + P3, P2, and to a lesser extent P3. This is in keeping with observations of the rotation curve of other clusters such as o Cen (e.g. Meylan & Mayor 1986; Merritt, Meylan & Mayor 1997; van de Ven et al. 2006; Sollima et al. 2009) and 47 Tuc (e.g. Meylan & Mayor 1986). We note that for population P3, it is possible that we miss the declining part of the rotation curve because of the spatial sampling and centrally concentrated distribution of that population. Interestingly, the inferred position of the rotation axis of the different populations considered is in agreement within $1\sigma$ uncertainties, as can be seen from Fig. 2 and Table 2.

The biggest kinematic differences are found when comparing the rotation curves of the P2 and P3 subsamples (Fig. 5) with very similar results obtained when comparing P3 with the rest of the cluster stars (P1 + P2). With the kinematics of population P1 less well constrained, we cannot identify any difference between the rotation curve of this population and that of P2 or P3 (see e.g. Fig. 6).

In Fig. 7, we illustrate the difference in the rotational amplitude of P2 and P3 by overlaying the posterior probability distribution of $A_{\text{rot}}$ for these two populations. To quantify this further, we show in Fig. 8 the posterior probability distribution of the difference in rotational amplitude between P3 and P2. This distribution peaks at $\sim 4 \text{ km s}^{-1}$ and is clearly skewed towards P3 having a larger rotational amplitude than P2, with a $98.4$ per cent probability that the rotation amplitude of P3 is larger.

To further illustrate the observed kinematic differences between P2, P3, and the cluster as a whole, we show in Fig. 9 the radial profile of $V_{\text{rot}}/\sigma_{\text{los}}$ for these samples averaged along specific lines of sight (with inclination angles of $i = 90^{\circ}$, $60^{\circ}$, and $30^{\circ}$ between the rotation axis and the line of sight) in order to give an idea of the degeneracy between inclination angle and intrinsic rotation. Note that the inclination angle of the rotation axis of M13 is not constrained observationally, but $i = 60^{\circ}$ was adopted as a rough estimate providing a satisfying agreement between observations and self-consistent rotating models by Lupton et al. (1987). To build the $V_{\text{rot}}/\sigma_{\text{los}}$ profiles as a function of projected distance $R$ from the centre of the cluster, we average the absolute value of $V_{\text{rot}}$ over all angles in the meridional plane (i.e. $x$–$y$ plane in Fig. 2) for a given $R$ and then divide by $\sigma_{\text{los}}(R)$. This is because for the assumed cylindrical rotation, $V_{\text{rot}}$ was defined above as a function of the distance from the rotation axis, not as a function of distance from the cluster centre.

$V_{\text{rot}}/\sigma_{\text{los}}$ of the whole sample (P1 + P2 + P3) peaks at a value of $\sim 0.4$ assuming $i = 90^{\circ}$, but the peak value could be as high as $\sim 0.7$ for a less favourable inclination of $i = 30^{\circ}$. This peak occurs around 2 arcmin from the centre of the cluster, beyond which the $V_{\text{rot}}/\sigma_{\text{los}}$ profile is almost flat or possibly decreasing only very slightly within the range of our data. A similar flattening of the profile is found for the subsamples P2 and P3, with a peak value reached farther out ($\sim 5$ arcmin) for population P3. It is interesting to note the importance of ordered motions for population P3, with $V_{\text{rot}}/\sigma_{\text{los}}$ reaching a maximum of at least 0.5 but possibly even larger than 1 or 2 when considering statistical uncertainties and the unconstrained inclination of the rotation axis. In comparison, the maximum $V_{\text{rot}}/\sigma_{\text{los}}$ for P2 is generally at most $\sim 0.5$ or lower.
Figure 9. Ratio of the mean rotational amplitude over the 1D velocity dispersion as a function of projected distance from the centre of the cluster for the subsamples P1 + P2 + P3 (left-hand panels), and P2 and P3 (right-hand panels), and adopting an inclination angle of 90°, 60°, or 30° (from the top to bottom) between the rotation axis and the line of sight. Best fits are shown as solid lines with shaded regions illustrating the 1σ uncertainty envelopes of the $V_{rot}/\sigma_{los}$ profiles.

4 DISCUSSION

4.1 Possible sources of contamination to the rotation signature

Before discussing the interpretation of the rotational signature reported in the previous section, we consider here possible sources of contamination that could affect our observations and introduce a spurious rotational signal in our radial velocity data set.

One of these is a possible alignment of tidal tails with the line of sight, which could mimic a gradient in the mean radial velocity across the cluster (otherwise attributed to rotation) if the leading and trailing tails are seen in projection on the cluster. Stars just escaping from the Lagrange point towards the Galactic Centre (for the Lagrange point closest to the Galactic Centre) or in the direction opposite to the Galactic Centre (for the Lagrange point farthest from the Galactic Centre) could also act as a source of contamination.

To verify possible line-of-sight alignments of the tidal tails or Lagrange points of M13, we investigate the orientation of the cluster’s orbit and Lagrange points. The present-day velocity and uncertainty were taken from Dinescu, Girard & van Altena (1999). We perform 200 orbit integrations using GALPY (Bovy 2015) in the MWPOTENTIAL2014 potential. Each orbit realization assumes a velocity sampled from a normal distribution with mean and dispersion equal to the literature value and uncertainty. In Fig. 10, the black lines show the orientation of possible orbits for M13 in equatorial coordinates and also in a Galactocentric Cartesian frame with $R_\odot = 8.3$ kpc, $y_\odot = z_\odot = 0$ in the top view ($x-y$) and the side view ($x-z$). The blue (red) dot shows the orientation of the Lagrange point...
that is less (more) distant from the Galactic Centre. These have been offset from the cluster centre by 0.5 kpc for illustration purposes. In this configuration, stars escaping from the less (more) distant Lagrange point would have radial velocities that are blueshifted (redshifted) with respect to the systemic radial velocity of the cluster. The positions of the sun, M13, and the Galactic Centre are also indicated in Fig. 10, and the line of sight is shown with a dashed line.

From this analysis, we infer that there is no alignment with the line of sight from the tidal tails or the Lagrange points. We cannot discard that there is some overlap of escaper stars with the line of sight, but given the geometry of the orbit of M13, these would be mainly observed in the outskirts of the cluster. The fact that the rotation curve of M13 peaks at intermediate radii and then declines farther out argues against the idea that these escapers in the outskirts of the cluster constitute a significant source of contamination to the rotation signal from escaper stars in the outskirts of the cluster because we would otherwise expect the least centrally concentrated populations (P1 and P2) to be the most affected. Finally, given that stars escaping from clusters are preferentially lower mass stars, it is doubtful that a large population of escapers would contaminate our sample of giants, unless the cluster has lost a large fraction of its mass. The present-day mass function of M13 ($\alpha = -0.98 \pm 0.02$ for $0.3 \lesssim m \lesssim 0.8 M_\odot$, with $d\nu/dm \propto m^\alpha$; Paust et al. 2010) is not strongly depleted in low-mass stars and is indeed consistent with the cluster having lost less than $\sim 30$ per cent of its initial mass due to two-body relaxation (Trenti, Vesperini & Pasquato 2010), so we expect the mean mass of the escaper stars to be much lower than the typical mass of our observed giants. Tides can also give rise to rotation inside the cluster because unbound stars on retrograde orbits (with respect to the direction of the cluster’s orbit) are more stable against escape than prograde orbits (e.g. Tiongco, Vesperini & Varri 2016). However, the resulting rotation signature would be close to solid-body rotation and stronger in the outer parts of the cluster, contrary to our observations for the same reasons as outlined above.

Another effect could potentially introduce a spurious rotational signal, but it is expected to be most important in objects with a larger angular extent on the sky such as dwarf spheroidal satellite galaxies of the Milky Way. In these extended objects, the mean line-of-sight velocity of a star will depend on the position of the star because of geometrical projection effects due to the proper motion of the object, introducing a velocity gradient mimicking solid-body rotation (e.g. Battaglia, Helmi & Breddels 2013). Note again that the rotation curve of M13 appears to peak at intermediate radii and is not solid-body all the way to the outer parts of the cluster as would be expected if this geometrical effect was important. Moreover, the spurious solid-body rotation expected in this case would result in a velocity field with a velocity gradient parallel to the proper motion direction. From a joint inspection of Figs 2 and 10 (left-hand panel), we can see that this is not the case and that the velocity gradient across the cluster is actually almost perpendicular to the orbit of the cluster projected on the sky. We thus conclude that the rotation signature detected is not the result of geometrical/projection effects.

4.2 Global rotation of M13

The clear global rotation signal that we detected in M13, with an amplitude of $A_{\text{rot}} = 2.7^{+0.9}_{-0.8}$ kms$^{-1}$, is consistent with the rotation curve obtained by Lupton et al. (1987, see their fig. 5) from a similar sample size but with less precise radial velocity measurements. These authors also report a 1D central velocity dispersion in the giants of $\sim 7$ kms$^{-1}$, consistent with our inferred central velocity dispersion of $\sigma_0 = 6.6^{+0.8}_{-0.6}$ kms$^{-1}$. From Integral Field Unit (IFU) observations, Fabricius et al. (2014) measured a central velocity gradient of $||\nabla v|| = 1.7 \pm 0.1 \pm 0.1$ km s$^{-1}$ arcmin$^{-1}$ (attributed to cluster rotation) in the inner $\sim 1$–2 arcmin of M13. This is in excellent agreement with the central velocity gradient $||\nabla v|| \approx 1.8$ km s$^{-1}$ arcmin$^{-1}$ implied by the best-fitting rotation curve of our full sample [where $||\nabla v|| = \delta (V_{\text{rot}} \sin i (X_{\text{rot}}))/\delta X_{\text{rot}} |_{X_{\text{rot}}=0} = 2A_{\text{rot}}/R_{\text{peak}}$]. Note that our spectroscopic data do not probe as far in as the IFU data of Fabricius et al. (2014), but the good match between their observed central velocity gradient and the one implied by our best-fitting rotation curve lends further support to our assumption of solid-body rotation in the inner parts of the cluster.

Figure 10. Orbit realizations (solid black lines) in the Milky Way potential for the GC M13, with variations between the different realizations capturing the uncertainty in the measured velocity of the cluster. The orbits are shown in the plane of the sky in equatorial coordinates (left-hand panel), and in the Galactocentric Cartesian frame ($R_\odot = 8.3$ kpc; $\gamma$, $\zeta = 0$) as a top view ($x$–$y$ plane; middle panel) and side view ($x$–$z$ plane; right-hand panel). The position of the sun is indicated with a black circle, the Galactic Centre with a black triangle, M13 with a black plus sign, the line of sight with a dashed line, and the blue and red circles mark the position of the Lagrange points, which have been offset from the cluster centre by 0.5 kpc in this schematic picture.
The PA of the rotation axis reported by Fabricius et al. (2014), $\text{PA}_0 = 16.5 \pm 3.6 \pm 7.8$, is also perfectly consistent with our inferred value of $\text{PA}_0 = 14.1^\circ$. M13 not only rotates, but it is also somewhat oblate. This flattening was first observed using Palomar Sky Survey prints by Kadla et al. (1976), who presented a curve of flattening and PA of the semimajor axis as a function of distance from the centre. They found that the axial ratio of isodensity contours falls from around 1.0 at small radii ($\sim 0.7$ arcmin) to about 0.85 at 6 arcmin, with the PA of the semimajor axis remaining roughly constant at $\sim 110 - 120^\circ$. Fabricius et al. (2014) also derived the central ellipticity and PA for the best-fitting ellipsoid using published catalogues of the ACS survey of GCs. In the inner 100 arcsec, they measured an ellipticity of $\sim 0.02$ (i.e. axial ratio of $\sim 0.98$) with a PA for the semimajor axis of $115.8 \pm 3.8 \pm 16.8$. These PAs for the major axis of the photometric ellipsoid are consistent with being shifted by 90$^\circ$ from the PA of the rotation axis, in agreement with what is expected if internal rotation is responsible for the flattening of the cluster.\footnote{Fabricius et al. (2014) actually report $\text{PA}_{\text{kin}} = 106.5$, but in the convention adopted by these authors, we would have $\text{PA}_0 = \text{PA}_{\text{kin}} - 90^\circ = 16.5$.} This idea is further supported by the rotating distribution-function based models of M13 by Lupton et al. (1987), which show a reasonable agreement with the observed variation of the axial ratio of isophotes as a function of the semimajor axis (based on the data by Kadla et al. 1976). The best-fitting models of M13 from Lupton et al. (1987) also have a PA of $130^\circ \pm 15^\circ$ for the semimajor axis, which is consistent with the measurements referenced above. However, note that other measurements of the PA of the photometric semimajor axis appear discrepant from the ones listed above. White & Shawl (1987) and Chen & Chen (2010) found a PA for the semimajor axis of 52$^\circ$ and 162$^\circ$, respectively, with approaches sensitive to the inner (White & Shawl 1987) and outer parts of GCs (Chen & Chen 2010). The two studies report an axial ratio of 0.89 and 0.88, respectively. Note that the White & Shawl (1987) work is based on optical data, while Chen & Chen (2010) is based on the spatial distribution of 2MASS point sources (i.e. infrared), and differences in the PA from these two studies are frequent.

M13 is only one example in a long and growing list of GCs showing evidence of internal rotation and/or deviations from sphericity (e.g. Geyer, Nelles & Hopp 1983; Meylan & Mayor 1986; White & Shawl 1987; Gebhardt et al. 1994; Peterson & Cedworth 1994; Meylan & Heggie 1997; van Leeuwen & Le Poole 2002; Anderson & King 2003; Chen & Chen 2010; Lane et al. 2010; Bellazzini et al. 2012; Bianchini et al. 2013; Fabricius et al. 2014; Kacharov et al. 2014; Lardo et al. 2015). That said, the link between rotation and flattening is not necessarily obvious because other factors such as pressure anisotropy and Galactic tides can lead to flattening (e.g. Stephens, Catelan & Contreras 2006; van den Bergh 2008). A simple and commonly used tool to estimate the importance of rotation in shaping the morphology of GCs is to place them in the $V_{\text{rot, max}}/\sigma_0$ versus $\epsilon$ diagram, where $V_{\text{rot, max}}/\sigma_0$ is the ratio of the observed maximum of the line-of-sight rotation profile to the central line-of-sight velocity dispersion $\sigma$ and $\epsilon$ is the (global) ellipticity. We note that this approach is no substitute to detailed dynamical modelling because it compares only global quantities, while rotation and ellipticity can vary significantly with radius as the anisotropy parameter changes, and the position of a cluster in the $V_{\text{rot, max}}/\sigma_0$ versus $\epsilon$ diagram is also sensitive to inclination effects (see discussion in Bianchini et al. 2013). The position of a cluster in the diagram is often compared with the relation between $V_{\text{rot, max}}/\sigma_0$ and $\epsilon$ expected for oblate rotators viewed ‘edge-on’ (Binney 2005; Cappellari et al. 2007). Assuming an average ellipticity of $\sim 0.9$ for M13 (see above), and estimating $V_{\text{rot, max}}/\sigma_0 \approx 0.4 \pm 0.1$ from the values of Table 2 for the whole sample (and bearing in mind inclination effects), we find that M13 is in good agreement with the expected relation for an isotropic oblate rotator (comparing, for example, with figures from Bianchini et al. 2013; Kacharov et al. 2014). This suggests that the flattening is consistent with being caused by internal rotation. A value of $V_{\text{rot, max}}/\sigma_0 \approx 0.4 \pm 0.1$ also places M13 among the GCs having the largest fraction of energy in rotation. This evidence and the remaining discrepancies discussed above (e.g. mismatches between the position of the semimajor axis from different studies) call for a more detailed study modelling the interplay of rotation, pressure anisotropy, Galactic tides, and flattening in this cluster, which will be helped by the precise radial velocities reported here and future proper motions from the Gaia satellite. This is, however, beyond the scope of this paper.

Another useful diagnostic is the ratio of rotational amplitude to velocity dispersion as a function of radius (Fig. 9). Based on evolutionary 2D Fokker–Planck models of rotating clusters, we expect the $V_{\text{rot}}/\sigma$ profile to reach a maximum between about 1 and several half-mass radii and then decrease with increasing radius (Kim et al. 2002; Fiestas et al. 2006). Such a profile has been observed in other clusters like $\omega$ Cen and 47 Tuc (Meylan & Mayor 1986), and is qualitatively consistent with what we observe in M13.\footnote{When comparing our $V_{\text{rot}}/\sigma$ profile with those of Fiestas et al. (2006) and Kim et al. (2002), note that our $V_{\text{rot}}/\sigma$ values may be underestimated because of the way we define $V_{\text{rot}}$ compared with these authors. Our understanding is that they represent $V_{\text{rot}}$ as the azimuthal velocity evaluated on the equatorial plane, while we average the rotational velocity over all angles in the meridional plane. With our assumed cylindrical rotation, this yields lower values of $V_{\text{rot}}$ at a given radius than if we reported the rotational velocity on the equatorial plane.} As a cluster evolves, it loses mass and angular momentum, and the radial position of the peak of the $V_{\text{rot}}/\sigma$ profile will move outwards. The maximum value of $V_{\text{rot}}/\sigma$ at $r$ gives the dynamical age of the cluster (Kim et al. 2002). Together, these features can provide useful constraints on evolutionary models and may allow to put limits on the initial amount of rotational energy in clusters. For example, the relatively flat $V_{\text{rot}}/\sigma$ profile of M13 over several half-mass radii along with its modest maximum $V_{\text{rot}}/\sigma$ value (even when considering more favourable inclination angles) could be indicative of a post-core-collapse stage for this cluster, but we note that it is rather speculative and based solely on a qualitative comparison with the results of Kim et al. (2002, see their fig. 16). Detailed comparison with evolutionary models will be necessary to quantify this further.

4.3 Connection between global rotation and multiple populations

There may exist important connections between rotation and the formation of GCs and their multiple populations. While today the amount of rotational energy in clusters is typically not dominant, it is also not negligible ($0 < V_{\text{rot}}/\sigma < 0.5$, e.g. Meylan & Heggie 1997), and it could have been much more important initially

---

\footnote{Kadla et al. (1976) also suggest that the cluster may be slightly prolate in the very central parts (radii less than 0.7 arcmin), but these results should be considered uncertain due to the small number of stars contributing to the light in these regions (see discussions in Lupton et al. 1987).}

\footnote{For detailed examples of the connection between rotation and flattening in the GCs $\omega$ Cen and 47 Tuc, see Bianchini et al. (2013).}
because rotation is progressively wiped out as clusters evolve dynamically. Rotation is a natural consequence of the cluster formation process from the collapse of a star-forming cloud with net angular momentum, and differential rotation would naturally arise in star clusters that form by undergoing the process of violent relaxation in the tidal field of their host galaxy (Vesperini et al. 2014). Significant rotation at birth may be a ubiquitous property of GCs, and therefore rotation could be a key ingredient for understanding the widespread phenomenon of multiple populations in GCs (e.g. Bekki 2010; Hénault-Brunet et al. 2015; Mastrobouno-Battisti & Perets 2016).

Based on a sample of 25 Galactic GCs, Bellazzini et al. (2012) reported possible correlations between global rotation (specifically, \(A_{\text{rot}}\) and \(A_{\text{rot}}/\sigma_0\), where \(A_{\text{rot}}\) is a proxy of the mean rotational amplitude) and other cluster properties, some of which are sensitive to the characteristics of multiple populations in GCs.

They suggested that there may be a weak anticorrelation between \(A_{\text{rot}}/\sigma_0\) and the inter quartile range (IQR) of the Na–O anticorrelation [a parameter defined by Carretta (2006)] to measure the extension of the Na–O distribution in clusters and thus directly related to the properties of multiple populations. The suggested trend is such that clusters having a larger \(A_{\text{rot}}/\sigma_0\) show a less extended Na–O anticorrelation. With a large \(V_{\text{rot}}/\sigma_0\) and a very extended Na–O anticorrelation, M13 does not support this suggestion, and is instead similar to other outliers of such a possible trend like the peculiar NGC 2808 and \(\omega\) Cen.

A somewhat clearer trend was reported by Bellazzini et al. (2012) between \(A_{\text{rot}}/\sigma_0\) and metallicity ([Fe/H]), with higher metallicity clusters having typically larger values of \(A_{\text{rot}}/\sigma_0\). M13 does not really strengthen that conclusion with its high \(A_{\text{rot}}/\sigma_0\) compared to all other clusters in the moderately metal-poor regime around \([\text{Fe/H}] = -1.5\).

Another correlation was found by Bellazzini et al. (2012) between \(A_{\text{rot}}/\sigma_0\) and the horizontal branch morphology parameter \(\left(\frac{B-R}{E(R-I)}\right)\), with GCs having a bluer horizontal branch typically displaying lower \(A_{\text{rot}}/\sigma_0\). Metallicity is the most important parameter in shaping the morphology of the horizontal branch (e.g. Lee, Demarque & Zinn 1990), so it might play a role here as well, but since this correlation with the horizontal branch morphology parameter was found to be stronger than the correlation between \(A_{\text{rot}}/\sigma_0\) and \([\text{Fe/H}]\), there are likely additional parameters at play. Possible additional parameters include age and/or chemical abundance differences (in particular He) linked to variations in the properties of multiple populations (e.g. VandenBerg et al. 2013). In any case, M13 is a clear outlier that does not fit this picture with a large \(A_{\text{rot}}/\sigma_0\) despite its bimodal and extremely blue horizontal branch with \(\frac{B-R}{E(R-I)} = 0.976\) (Sandquist et al. 2010).

Finally, note that Bellazzini et al. (2012) also found significant correlations between the amplitude of rotation \(A_{\text{rot}}\) and some intrinsic cluster properties (namely \(\frac{B-R}{E(R-I)}\), \(M_V\), \(\sigma_0\), and \([\text{Fe/H}]\); with \(M_V\) and \(\sigma_0\) both tracing cluster mass). The correlation of \(A_{\text{rot}}\) with the horizontal branch morphology parameter was found to be particularly strong, but even stronger and more significant was the correlation of \(A_{\text{rot}}\) with two linear combinations of parameters: \(\frac{B-R}{E(R-I)} + 0.47 M_V\) and \(M_V - 1.73 [\text{Fe/H}]\). With \(M_V\) found to correlate with the level of He enrichment (brighter clusters typically have larger He abundance spreads; Milone 2015) and also found to play a role in bivariate correlations involving parameters related to the anticorrelation phenomenon (Carretta et al. 2009), all these possible relations hint at a complex interplay between cluster mass, rotation, and the chemical properties of multiple populations. Investigating the kinematics of subpopulations in massive and rapidly rotating GCs with distinct or extreme chemical patterns like M13 may help to unveil some of the details behind this interplay.

### 4.4 Difference in the rotational amplitude of multiple populations: implications for formation scenarios

The multiple populations of M13 are not fully mixed (the extremely O-depleted population is more centrally concentrated; Johnson & Pilachowski 2012), as expected based on its relatively large mass of \(~6\times10^5\ M_\odot\) (Leonard, Richer & Fahlman 1992), its Galactocentric radius of 8.4 kpc (Harris 1996), and a mass function that is not strongly depleted in low-mass stars suggesting only moderate mass-loss due to two-body relaxation (see discussion and references in Section 4.1). On that basis, it is also not surprising that we were able to detect kinematic differences between subpopulations (Hénault-Brunet et al. 2015).

But before we can establish that the observed difference in rotational amplitude between the multiple populations of M13 stems for the formation and early evolution of the cluster, we first need to consider whether this signature could simply be a product of dynamical evolution. This could happen if the distinct chemical populations also have different mean stellar masses. One way to achieve this is through differences in their initial He fraction. Using far-ultraviolet and optical CMDs from HST, Dalessandro et al. (2013) estimated a maximum helium abundance of \(Y = 0.3\) for stars in M13 (see also VandenBerg et al. 2013). Based on Dartmouth isochrones with \([\text{Fe/H}] = -1.5\), an age of 12.25 Gyr, and \([\alpha/\text{Fe}] = 0.4\) (VandenBerg et al. 2014) appropriate for M13, giants with normal He (\(Y = 0.247\)) have masses of 0.82 \(M_\odot\), while He-rich giants (\(Y = 0.33\)) have masses of 0.7 \(M_\odot\). Assuming that the extremely O-depleted giants in M13 are also the most He-enriched, we estimate that they would be about 0.1 \(M_\odot\) less massive than their He-normal counterparts.

The dynamical evolution of rotating clusters with two mass components or a mass spectrum has been studied with Fokker–Planck models (Kim, Lee & Spurzem 2004), direct N-body simulations (Ernst et al. 2007), or both (Hong et al. 2013). From these studies, the main dynamical evolution process that would lead to a difference in rotational amplitude between different mass species actually causes the most massive stars in the central parts to rotate faster than lower mass stars. Two main factors are instrumental in determining the evolutionary behaviour of the rotational properties of the models: the transport of angular momentum within the radial extension of the system, as driven by collisional relaxation (which obviously takes place also in equal-mass systems) and the exchange of angular momentum between different mass species, in association with the tendency towards energy equipartition. The second factor is intrinsically linked to the process of mass segregation, i.e. the fact that more massive stars tend to become progressively more radially concentrated, as a result of their relaxation-driven evolution. In the presence of global internal rotation, the interplay between mass segregation and transport of angular momentum is highly non-trivial, but the investigations quoted above have already offered some evidence that heavier components become more centrally concentrated and are characterized by a higher angular velocity, compared to the lower mass component, which is spatially more diffuse and slower rotating. The two components then experience a rather different evolution, with the angular velocity of the heavier component increasing very rapidly during the early phases, while that of the lighter stars shows only a moderate increment (see fig. 6 from Kim et al. 2004). In addition, these results seem to have a significant dependence on the initial rotation strength of the systems (see also...
Hong et al. (2013), and it should be stressed that, in this context, the different mass components start with the same value of angular velocity.

From the mass differences estimated above for the extremely O-depleted (He-rich) giants compared with He-normal giants, the expected effect of dynamical evolution outlined above for multimag rotating systems is thus opposite to the difference in rotational amplitude that we detected in M13 (where the presumably less massive stars are rotating more rapidly). Moreover, differences in the peak rotational velocity of different mass species remain relatively small in the models of Kim et al. (2004) and Hong et al. (2013), despite much larger mass ratios between the different components, while we find that the peak rotational velocity of the extreme population is much larger (a factor of ∼4) than the peak rotational velocity of the other subpopulations. We thus argue that the faster rotation inferred for the extreme population (P3) in M13 is not, as far as we can tell, an effect produced by the long-term dynamical evolution of the cluster.

In a different context from multiple populations or mass species, Kim et al. (2002) mentioned another effect which could give rise to strong rotation for stars in the central regions of a cluster: Collisions between stars or binaries could produce such an effect since the collisions dissipate the relative kinetic energy of the colliding particles but conserve their net angular momentum in the cluster potential. If somehow the extreme O depletion and Na enrichment of population P3 can be linked to the formation of these stars via stellar mergers in the central regions of the cluster, in particular, during its early evolution when the cluster was much denser, then this would potentially explain the more centrally concentrated distribution of this population and its faster rotation. In such a scenario, we would expect the rotation axis of this extreme population to align with the rotation axis of the bulk of the cluster stars, which is consistent with what we observe in M13.

Through conservation of angular momentum, a faster rotation and more centrally concentrated distribution is also expected for a stellar population that would form from dissipative accretion of enriched gas on to the central regions of the cluster (e.g. Sandage & Fouts 1987). This is what Bekki (2010) also predicted in the context of self-enrichment of the cluster by AGB stars (e.g. D’Ercole et al. 2008). In Section 1, we pointed out one of the problems afflicting such a scenario, in particular, the mass budget problem. The mass budget problem would perhaps be less of a concern if only the extreme population was formed in this way, but it would not solve many of the other problems with AGB ejecta as a source of pollution, for example, the absence of gas, age spreads, or ongoing star formation in young massive clusters, and the cluster-to-cluster differences in the relative He and Na enrichment (Bastian 2015; Bastian et al. 2015). Plus, it would not address the question of how the rest of the Na-enriched stars (with less extreme O depletion) got polluted. In this scenario, we would also expect the rotation axis to be the same for different subpopulations.

The opposite difference in rotation trend is expected from a scenario in which the most enriched stars are the ones initially crossing the core of the cluster and preferentially on radial (low angular momentum) orbits (e.g. the early disc accretion scenario of Bastian et al. 2013). In this case, the rotational amplitude of the enriched stars at a given radius would be lower initially (assuming the cluster has some net rotation; see Hénault-Brunet et al. 2015), which is contradicted by our observations of the faster rotation of population P3 in M13. As mentioned in Section 1, this scenario is already disfavoured for other reasons.

5 SUMMARY AND CONCLUSIONS

We used radial velocities from spectra obtained with the WIYN telescope to probe the presence of kinematical differences among M 13 multiple populations. The existing chemical tagging (in particular, Na and O abundances) for our sample of stars coupled with the radial velocities measured in this work makes this data set well suited for this exploration.

We fitted a six-parameter kinematic model including rotation to the full data set and various chemical subsamples. In addition to improved constraints on the global rotation and importance of rotational support in M13, we found a significant difference in the rotational amplitude of different subpopulations. The most likely difference between the rotational amplitude of the extremely O-depleted population and the rest of the sample was found to be ∼4 km s\(^{-1}\) (with the extreme population rotating faster), with a 98.4 per cent probability that the rotational amplitude of this extreme population is larger than the rotational amplitude of the rest of the sample. We also find that the inferred PA of the rotation axis for the different subpopulations considered is consistent, within uncertainties, with the hypothesis that all subpopulations share the same rotation axis, although it must be said that the rotation axis of the ‘normal’ halo-like subpopulation is poorly constrained.

We suggested that the origin of such a kinematical signature in M13 is likely a signature imprinted early in the formation history of this non-fully mixed GC. This would open up the possibility to use kinematics to distinguish between different scenarios for the formation of multiple populations (e.g. Hénault-Brunet et al. 2015). We also argued, based on a previous modelling that explored the evolution of multigas rotating systems, that this signature is unlikely to result from the long-term dynamical evolution of the cluster and be caused by mean stellar mass differences between the subpopulations.

Given the modest size of our sample, it will be desirable to follow up on these findings and hopefully improve the statistical significance of the reported difference in the rotation signals of subpopulations. Building a larger sample (in particular, increasing the sample of O-depleted stars, which exhibit a stronger rotational amplitude in our data set) would benefit from a different observational strategy since chemical tagging using high-resolution spectroscopy is observationally expensive. An effective alternative method for tracing light-element abundance variations in GCs is based on photometry with narrow-band filters sensitive to C, N, and O abundances. This is the approach adopted by the Hubble Space Telescope UV Legacy Survey of Galactic GCs (Piotto et al. 2015), from which eventual catalogues of chemically tagged stars (which will include M13), complemented by Gaia proper motions and/or ground-based radial velocities, will facilitate a robust statistical exploration of the kinematical properties of Galactic GCs and their multiple populations.

Whether different degrees of rotation between chemical subpopulations in GCs is the norm or the exception remains to be studied on large samples of stars in more clusters. Similarly, whether the most O-depleted and Na-enriched stars systematically rotate faster...
than other subpopulations should be checked. Searching for these kinematic imprints and understanding why kinematic differences exist are crucial and necessary aspects of the study of GC formation and evolution.

ACKNOWLEDGEMENTS

We thank the anonymous referee for constructive comments. We would also like to thank Mark Gieles, Nate Bastian, and Nikolay Kacharov for useful discussions and/or comments on the manuscript. MJC and VH-B. acknowledge the hospitality of the Lorentz Center during the early stages of this collaboration. MJC gratefully acknowledges support from the Sonderforschungsbereich SFB 881 'The Milky Way System' (subproject A8) of the German Research Foundation (DFG). VH-B acknowledges support from the Radboud Excellence Initiative Fellowship. CAP gratefully acknowledges the support of the Kirkwood Research Fund at Indiana University. EB acknowledges financial support from the European Research Council (ERC-StG-335936, CLUSTERS). CJU gratefully acknowledges support from the Clay Fellowship, administered by the Smithsonian Astrophysical Observatory. ALV acknowledges support from the EU Horizon 2020 program (MSCA-IF-EF-RI 658088).

APPENDIX A: SUPPLEMENTARY FIGURES

For completeness, we show here 1D and 2D projections of the posterior probability distribution of the six free parameters of our kinematic model for the different subsamples considered.
Figure A1. Projections of the posterior probability distribution on the planes determined by every pair of parameters (see Section 3) of our kinematic analysis of the full sample of stars in M13 (P1 + P2 + P3). Contours indicate 1, 2 and 3σ levels. Histograms representing the marginalized posterior probability distribution of each parameter are also shown.
Figure A2. Same as Fig. A1, but for the subsample of ‘intermediate stars (P2).
Figure A3. Same as Fig. A1, but for the subsample of “extreme” stars (P3).
Figure A4. Same as Fig. A1, but for the subsample of ‘normal’ stars (P1).
Figure A5. Same as Fig. A1, but for the subsample of 'normal and 'intermediate stars (P1 + P2).
