ABSTRACT
One of the most frequent symptoms in multiple sclerosis (MS) is fatigue. It has a major impact on quality of life as well as on professional activity. Even nowadays it is still unclear what constitutes an adequate assessment of the perceived fatigue.

Introduction
Fatigue, with a prevalence of at least 65 % [1, 2], is one of the most common symptoms of multiple sclerosis (MS) and has far-reaching effects on the quality of life and employment, even statistically taking into account the degree of motor impairment [3]. Fatigue is a subjective sensation of lack of energy and exhaustion which can only be measured directly in the form of verbal reports. Due to its primarily subjective character, the concept of fatigue includes various aspects of human experience and behavior. Therefore, its measurement is mainly based on questionnaires and clinical interviews. It should be kept in mind that the structure of these 2 data collection methods depends on the internal model the researcher applies, which determines the content, number and direction of the questions posed to the patient with fatigue.

Despite the genuinely subjective sensation of fatigue, different methods are available to measure and diagnose it. These can be distinguished according to whether the pure state of fatigue is being measured or whether a change in feeling is being objectively or subjectively surveyed. The usual questionnaires gather data on the condition using subjective methodology, that is, responses to specific questions that categorize the current state [4]. They do not record the experienced change in fatigue in certain stressed or unstressed situations. Similarly, an attempt can be made to classify objective behavior. In the past, it was attempted to measure fatigue directly through the application of tests, comparing patients with and without fatigue while assuming different performance in the tests employed. On the other hand, focus was on the increase in loss of power and fatigue under continuous stress, with a measurement without fatigue while assuming different performance in the tests employed. On the other hand, focus was on the increase in loss of power and fatigue under continuous stress, with a measurement without fatigue while assuming different performance in the tests employed. On the other hand, focus was on the increase in loss of power and fatigue under continuous stress, with a measurement without fatigue while assuming different performance in the tests employed. On the other hand, focus was on the increase in loss of power and fatigue under continuous stress, with a measurement without fatigue while assuming different performance in the tests employed. On the other hand, focus was on the increase in loss of power and fatigue under continuous stress, with a measurement of either motor or cognitive effort. The following provides an overview of the results obtained through these methods. The focus is, of course, on the questionnaires for the assessment of fatigue, since these continue to be the core of the fatigue diagnostics.

Criteria for the Diagnosis of “Fatigue”
There are currently no uniform criteria for the clinical diagnosis of MS-related fatigue, but rather various recommendations for the definition of fatigue and the possibility of measurement using questionnaires. Therefore Kluger et al., relying on an earlier review article on fatigue [4], suggested criteria for determining fatigue in...
Table 1 Criteria for the diagnosis of MS-related fatigue based on criteria for determining fatigue in patients with Parkinson’s disease according to Kluger et al. Parkinson’s disease-related fatigue: a case definition and recommendations for clinical research. Mov Dis 2016; 31: 625–631 (5).

Criteria for the diagnosis of MS-related fatigue

Patients must report significantly diminished energy levels or increased perceptions of effort that are disproportionate to attempted activities or general activity level. Symptoms must be present for most of the day every day or nearly every day during the previous month. In addition, patients must have 4 or more of the symptoms from section A as well as meet criteria in sections B, C, and D.

A. Symptoms
1. Symptoms may be induced by routine activities of daily living.
2. Symptoms may occur with little or no exertion.
3. Symptoms limit the type, intensity, or duration of activities performed by the patient.
4. Symptoms are not reliably relieved by rest or may require prolonged periods of rest.
5. Symptoms may be brought on by cognitive tasks or situations requiring sustained attention including social interactions.
6. Patients avoid rigorous activities because of fear of experiencing worsening of symptoms.
7. Mild to moderate exertion may induce a worsening of symptoms lasting hours to days.
8. Symptoms have a predictable diurnal pattern regardless of activities performed (e.g., worsening in the afternoon).
9. Symptoms are unpredictable and may have a sudden onset.

B. Fatigue causes clinically-relevant stress in the patient or impairment of functional capacity in social, occupational or another important range of activities.

C. There is evidence from the history and physical examination suggesting fatigue is a consequence of multiple sclerosis.

D. Symptoms are not primarily a consequence of a comorbid psychiatric disturbance (e.g., depression), sleep impairment (e.g., obstructive sleep apnea) or other health issue (e.g., anemia, heart disease).

Questionnaires for Diagnosing Fatigue

Diagnosis of clinically-relevant fatigue

In recent years the functionality, validity and reliability of available German-language questionnaires for the measurement of fatigue have been analyzed and summarized in various reviews [6–14]. We shall refer to these reviews in order to briefly recap their results (presented in Table 2) and shall then discuss additional aspects. Further English-language methods can be found in Khan, Amatya and Galea [13].

The functionality of questionnaires depends on their purpose. The focus is on 2 diametrically opposed issues. On the one hand, using questionnaires can be used to distinguish patients who show clinically-relevant fatigue from those who show no clinically-relevant fatigue. Questionnaires devoted to this purpose should have appropriate cut-off values that allow such discrimination. They should take into account all relevant aspects of fatigue and, if possible, provide different related cut-off values. In our view, the WEIMUS, FSMC as well as the MFIS would be suitable (Table 2). On the other hand, the presence of motor and cognitive fatigue at time t1 predicts the development of cerebral atrophy or subclinical demyelination in the region of the corpus callosum as well as the relapse rate for the following 17 months. On the other hand, the presence of motor fatigue at time point t1 did not correlate with the rate of relapse or cerebral atrophy or subclinical demyelination in the region of the corpus callosum [15].
The varying dimensionality of the questionnaires could also be a reason that the correlation between different questionnaires is usually moderate but not necessarily high. Flachenecker et al. showed, for example, that the correlation between MFIS and FSS is in the range of $r = 0.56$, which corresponds to a shared variance of only 31%, which also means that substantial proportions of the variance detected are differently elucidated [16]. According to our data based on 168 patients with MS who were interviewed in the context of different research projects, FSS and FSMC total scores correlate with an $r$ of 0.76, which corresponds to a shared variance of approximately 60%.

Overall, however, it must be noted that comparative studies among the questionnaires and the external validity of the fatigue questionnaires are scarce, and even more rarely those which are concerned with the question of whether the grading of mild, moderate and severe fatigue is comparable and meaningful. However, the establishment of clinically-relevant fatigue would require precisely such external validation.

In the past, we carried out a series of studies that included, among other things, occupational activity and a whole series of questionnaires on fatigue, depression, sleep quality and daytime tiredness. We relied on the FSS and FSMC for the assessment of fatigue. The FSMC is the only fatigue questionnaire listed in ▶ Table 2 providing cut-off scores for grading the severity of fatigue. Breaking down our data of the 168 MS patients (see above) by the status of occupational activity: employed full-time ($n = 36$), working half-time ($n = 35$), not employed (generally women with children) ($n = 21$) and retired ($n = 76$) only the total value of the FSMC results in a significant difference among these groups, after statistical control. Retired people indicate significantly higher fatigue values than those in the employed groups. On the other hand, the results for the other questionnaires (as well as the FSS) are far from showing significant differences.

A corresponding validation of the fatigue scales would also be useful with regard to the clinical relevance of the proposed cut-off values, but the authors are unaware of such studies. In our database according to the FSS, 44.4% of MS patients with no fatigue (FSS < 4) were employed fulltime and 38.8% had at least moderate fatigue (FSS > 5). Among the retired, the ratio was 27.6 to 44.7%. For the FSMC total, the ratio for full-time employees was 16.7 to 44.4%, and for pensioners 3.9–80.3%. According to the FSMC, 92% of the pensioners suffer at least moderate fatigue (44.7% according to the FMS). These numbers show that the external validity of the severity classification of the FSMC significantly exceeds that of the FSS. However, 44.4% of full-time workers rate their fatigue as severe using the FSMC, thus documenting that the mere extent of reported fatigue should not be sufficient for deciding social-medical issues.

Fortunately, however, the reliability of most of the fatigue questionnaires in the reviews we have mentioned is considered to be adequate, as was shown by Flachenecker’s study (▶ Table 2) [6].

Regarding the practical aspect of the different amounts of time required to complete the questionnaires, in our view they all fall within a reasonably tolerable range (approx. 5–10 min).

### Assessment of clinically-relevant changes in fatigue experience

Most fatigue questionnaires are not designed to assess short-term changes in the experience of fatigue (e.g., immediately after a relaxation exercise or 1–2 h after administration of L-dopa) because they presuppose internal averaging of the experience over a period of time (refer to the relevant user instructions). Because of this, researchers usually rely on so-called visual analog scales. However, this change to another mode of representation is less useful, since different studies show that such analog scales correlate weakly to moderately to more comprehensive fatigue scales.

FSS: Fatigue Severity Scale, WEIMUS: Würzburger Erschöpfungs-Inventar bei Multipler Sklerose, (Würzburger Fatigue Inventory for Multiple Sclerosis), FSMC: Fatigue Scale for Motor and Cognitive Functions MFIS: Modified Fatigue Impact Scale
Conventional fatigue scales can also be used for change measurement if assessment of a longer-term intervention with a gap of at least 2 weeks is needed. However, little or nothing is known about their sensitivity and specificity in the detection of changes in fatigue experience. Based on the literature, Learmonth et al. concluded that the FSS is suitable for measuring changes in the fatigue experience, although no corresponding information is available for most of the other scales [7]. In our non-interventional follow-up study [15], in which MS patients as well as healthy controls were examined at 2 time points at an interval of 17 months with respect to existing fatigue symptoms as well as changes in imaging, a relatively high correlation was found for the subscales of the FSMC, whereas the FSS did not demonstrate high time stability (Fig. 1).

Likewise, the study by Johansson et al. showed a marked fluctuation of fatigue experienced over time when assessed with the FSS [17]. Given the absence of an external criterion and the lack of targeted observation studies, it is impossible to indicate whether this variation in FSS values is an expression of higher change sensitivity or inaccurate measurement. In any case, our results show that a change in fatigue measured with the FSMC would have a high significance, as the values in this questionnaire obviously fluctuate little over time.

A study by Learmonth et al. to determine the psychometric properties of FSS and MFIS over 6 months also measured clinically-relevant change. For the FSS, 1.9 points (38% of the total score) indicate a clinically-relevant change. For the MFIS, 20.2 points are necessary to achieve a clinically-relevant change in the score [7].

Svenningsson, Falk, Celcius et al. [18] investigated the effect of natalizumab on the perception of fatigue. The FSMC was used to assess subjectively perceived fatigue, and a change of 9 points in the total score was considered clinically-relevant.

Lacking further studies, the definition of clinically-relevant changes in fatigue questionnaires is largely subjective. If classification is based on the degree of severity, the score between two degrees of severity could be considered as clinically relevant, pragmatically. In the case of the FSMC this would be 6 points per scale (that is, for the cognitive and motor scale). If a change of ½ SD would be considered clinically relevant for the FSMC, then according to our data, this would represent a change of 4 points. This corresponds with the classification of Svenningsson, Falk, Celcius et al., since the calculated 4 points per subscale necessary for a clinical change coincide almost with the 9 points necessary for the overall scale [18].

For the FSS a change by one average point would be relevant (i.e., between light fatigue, FFS value of 4, and moderate fatigue with an FFS value of 5).

Measurement of the responsive experience of fatigue

Distinguishing between patients with and without fatigue is an issue in everyday clinical practice. A measure of the subjective increase in fatigue under standardized conditions would be of great importance for the assessment of socio-medical questions as well as for the relationship between fatigue and tiredness. In principle this issue would relate to psychophysics. Which standardized change in the objective burden or relief of MS patients corresponds to what difference in fatigue?

In fact, there have been very few attempts at such a psychophysical measurement of fatigue; for the most part fatigue and the manifestation of fatigue at time of onset are purely additive. Thus Moller et al. [19] demonstrated that with subjectively the same motor effort, healthy controls and MS patients respond with the same degree of additional fatigue over time. The induced fatigue after motor stress was as high in non-patients as in MS patients and was therefore additive to the fatigue at the time of onset. Similar results were also obtained by Lehmann et al. in a cross-over experiment in which MS patients and healthy controls spent over 10 min on a working memory task, then watched a stimulating or relaxing video sequence before resuming the working memory activity [20]. The group which was first allowed to relax, then received stimulation, while the other group was allowed to relax. The result showed that the extent of induced fatigue was the same in all groups (the MS group was divided into those with and without fatigue) and also did not depend on the interim conditions. In the past we systematically analyzed the existing literature on this topic [21]. Overall, there is so far no significant evidence that MS patients and healthy

![Fig. 1](image-url) Correlation of fatigue values of the Fatigue Severity Scale (FSS) a as well as the total value of the Fatigue Scale for Motor and Cognitive Functions (FSMC) b at the start of the study (t1) as well as after 17 months (t2) [15].
controls differ in the increase in fatigue experience when they are equally burdened. Those MS patients starting at a higher initial level do not differ in relative increase.

Measurement of Fatigue using Neuropsychological Test Procedures

At its core, fatigue is a vegetative-cognitive syndrome [4], correspondingly it is presumed that fatigue is best measured using neuropsychological tests, thus enabling identification of chronic traits of patients with fatigue to perform worse because their fine motor performance is already in use in some clinics as a procedure for testing the capability to work [31]. Based on this group of studies, as well as those on the influence of cognitive stress and time of day on performance shown in reviewed studies, measuring fatigue using neuropsychological testing is highly complex [21, 22]. To do this, ence did not relate to the characteristic value of phasic alertness, 2 strategies must be distinguished. On the one hand, cognitive differences between patients with fatigue must be compensated by a previous acoustic cue [26]. The studies by Weinges-Evers, Brandt, Bock et al. [27] are an exception. They found a correlation between performance in the TAP and the narrower sense [21, 23, 24]. Even if many of these studies suffer from methodological problems, such as consisting of clinical tests constructed for totally different purposes applied on MS-patients with fatigue, they demonstrate the same basic trend, not showing a relation between subjective fatigue and cognitive performance. Inspired by animal experiments, theoretically motivated replication would be desirable, e.g., between contextually in-strategy in the measurement of fatigue analyzes the effect on the influenced memory performance and those without the requirement test process, the so-called time-on task effect, and this could for consideration of context-related information [25]. Neverthe- actually represent a central variable [33]. Fot the PASAT several irrelevant studies have been established, it is not possible to search groups have shown (although not always reproducible) that distinguish MS patients with fatigue from those who do not suffer the MS patients with fatigue show a stronger performance decline from fatigue by using test batteries according to current knowledge.

On the other hand, tests, which focus on sustained attention, i.e. holding attention over a period of time, or vigilance, i.e. maintaining slowed response time from 20 min onwards and, in some cases, an attention in the face of monotony, seem to be an exception in this increased rate of disregard of critical stimuli. Prior studies on alertness-testing indicated that their sensitivity is high if testing is repeated until such groups have been shown to be possible to search groups have shown that fatigue is reflected in the measurement of fatigue and time of day on performance shown in the Alertness Test, but not in the testing of selective attention [32].

However, methodological problems limit the value of the results. The correlative relationship between fatigue experience and About 30 years after Krupp et al. designed the Fatigue Severity Scale, adequate measurement of fatigue remains a central problem. Scale [9], in tests that vary very finely in time, this correlation can cause pa-ram for the clinical practice. Similar to other symptoms (such as depression) which recur due to purely internal sensations, diagnosis is insufficient. Clinical judgment based each entry in Table 1 is occurs if patients with cognitive fatigue are compared with healthy recommended for diagnosis. This presumes targeted questioning only and a comparison with MS patients without cognitive of the patient. Utilizing questionnaires supports clinical judgment.}

Summary

The present of fatigue does not mean that the decline of the reaction time can be attributed to the existing cognitive fatigue. It cannot be ruled out that the slowing of reaction times is related to the disease multiple sclerosis itself.

Moreover, in some of these studies the degree of depression was not always subject to adequate statistical controls [28]. Claros-Salinas, Dittmer, Neumann et al. [29] as well as Neumann, Sterr, Claros-Salinas et al. [26] excluded patients with moderate to severe depression, but their analysis did not take into account the BDI-II value, so that the effect of mild depression cannot be fully ruled out [4]. However, as 2 reviews have shown, measuring fatigue using (see [26, 29]). In addition, the correlation with the fatigue experience is insufficient. Studies such as these are an indication that the TAP Alertness procedure. The presence of fatigue does not mean that the effect on the influenced memory performance and those without the requirement test process, the so-called time-on task effect, and this could for consideration of context-related information [25]. Neverthe- actually represent a central variable [33]. Fot the PASAT several irrelevant studies have been established, it is not possible to search groups have shown (although not always reproducible) that distinguish MS patients with fatigue from those who do not suffer the MS patients with fatigue show a stronger performance decline from fatigue by using test batteries according to current knowledge. These remarks concern only the direct application of relatively short tests for the objectification of fatigue as well as test batteries. The group of vigilance tests could also be demonstrated (with a nota- ably higher replication rate) that MS patients with fatigue show a holding attention over a period of time, or vigilance, i.e. maintaining slowed response time from 20 min onwards and, in some cases, an attention in the face of monotony, seem to be an exception in this increased rate of disregard of critical stimuli. Prior studies on alertness-testing included nes testing indicated that their sensitivity is high if testing is repeated until such groups have been shown to be possible to search groups have shown that fatigue is reflected in the measurement of fatigue and time of day on performance shown in the Alertness Test, but not in the testing of selective attention [32]. Based on this group of studies, as well as those on the influence of cognitive stress and time of day on performance shown in the Alertness Test, but not in the testing of selective attention [32]. This test is already in use in some clinics as a procedure for testing the capability to work [31].

However, methodological problems limit the value of the results. The correlative relationship between fatigue experience and About 30 years after Krupp et al. designed the Fatigue Severity Scale, adequate measurement of fatigue remains a central problem. Scale [9], in tests that vary very finely in time, this correlation can cause pa-ram for the clinical practice. Similar to other symptoms (such as depression) which recur due to purely internal sensations, diagnosis is insufficient. Clinical judgment based each entry in Table 1 is occurs if patients with cognitive fatigue are compared with healthy recommended for diagnosis. This presumes targeted questioning only and a comparison with MS patients without cognitive of the patient. Utilizing questionnaires supports clinical judgment. As Using the FFS exclusively appears insufficient to get an impression
of the experience of fatigue. Due to more extensive evaluation, the WEIMUS is recommended as well as the FSMC for the German-speaking region. Both differentiate between motor and cognitive fatigue. In addition, the assessment of depression, sleep quality and daytime sleepiness is supported by questionnaires such as the Beck Depression Inventory [35] (excluding the somatic items), the Hospital Anxiety and Depression Scale (HADS) [36] the Pittsburgh Sleep Quality Index (PSQI) [37] and the Epworth Sleepiness Scale (ESS) [38]. In terms of research, external validation of the degrees of severity of the fatigue scales, for example, decisions relating to shortening working hours, represents a simple to accomplish –but urgently necessary – task.

In addition to surveying MS patients, objectification of the fatigue experience should be attempted through psychological testing. This is the case because the experience of fatigue as such is not equivalent to the inability to work, which must be subject to a separate consideration; conversely, cognitive deficits can also be present without the presence of fatigue. In the context of neuropsychological research, in addition to the determination of cognitive performance, the assessment of performance under monotony is a focal point. Vigilance tests requiring maintenance of continuous attention should especially be able to identify patients suffering from fatigue. If this is the case, then, from a social-medical point of view, this should be a reason to consider whether full-time employment is still possible or if a complete withdrawal from working life should be considered.

In the area of the objective assessment of motor fatigue, the kinematic gait analysis, in which the gait pattern before and after a motor task is compared [39], is used to measure the severity or the presence of motor fatigue. So far, no correlation with subjective motor fatigue has been found, so further validating studies are needed.

Objectification of the fatigue experience plays a role beyond social-medical decisions. Recent studies show that the experience of fatigue could also play a prognostic role in whether MS patients will experience a relapse in the coming months [15], will change from CIS status toward a diagnosis of MS [40] or suffer increased cerebral atrophy [15, 41, 42]. Furthermore, there are very limited indications that the choice of immunomodulatory medication may have an effect on the fatigue experience [43]. Therefore, additional studies on the improved detection of fatigue are still urgently required in 2017.
