Measurement of the $\bar{t}t$ production cross section in the $\tau + \text{jets}$ final state in $pp$ collisions at $\sqrt{s}=8$ TeV using the ATLAS detector

M. Aaboud et al.*
(ATLAS Collaboration)
(Received 1 March 2017; published 7 April 2017)

A measurement of the inclusive $pp \to \bar{t}t + X$ production cross section in the $\tau + \text{jets}$ final state is presented. The measurement is performed using 20.2 fb$^{-1}$ of proton-proton collision data recorded at a center-of-mass energy of $\sqrt{s} = 8$ TeV with the ATLAS detector at the Large Hadron Collider. The cross section is measured via a counting experiment by imposing a set of selection criteria on the identification and kinematic variables of the reconstructed particles and jets, and on event kinematic variables and characteristics. The production cross section is measured to be $\sigma_{\bar{t}t} = 239 \pm 29$ pb, which is in agreement with the measurements in other final states and the theoretical predictions at this center-of-mass energy.

DOI: 10.1103/PhysRevD.95.072003

I. INTRODUCTION

An important component of the Large Hadron Collider (LHC) [1] physics program is the measurement of the properties of the top quark, which is the most massive fundamental particle observed to date. With approximately one top-quark pair produced every second, the data sample used in this analysis is significantly larger than previously available samples, allowing for precise measurements of top-quark properties using final states that were previously limited by their statistical uncertainty. This article reports a measurement of the $\bar{t}t$ production cross section in the $\tau + \text{jets}$ final state, where the hadronic final states of the $\tau$ lepton ($\tau_{\text{had}}$) are used exclusively. This measurement, which is of comparable precision to the $\mu + \text{jets}$ and $e + \text{jets}$ cross-section measurements by the ATLAS Collaboration [2], provides a cross-check of the $\bar{t}t$ production cross-section measurements in the other final states. In addition, differences between measurements or between measurement and theory could lead to the discovery of non-Standard-Model physics or to limits on its possible extensions. Previous measurements in this final state have been performed by the D0 [3] and CDF [4] collaborations at the Tevatron operating at $\sqrt{s} = 1.96$ TeV and by the ATLAS [5] and CMS [6] collaborations at the LHC operating at $\sqrt{s} = 7$ TeV. Besides the measurement in the $\ell' + \text{jets}$ ($\ell' = e, \mu, \tau$) final state at $\sqrt{s} = 8$ TeV, the $\bar{t}t$ production cross section has also been measured in the dilepton ($e^+e^-, \mu^+\mu^-$, and $e^\pm\mu^\mp$) final state by the ATLAS and CMS collaborations [7,8]. Since the different channels in which this measurement has been performed have different backgrounds and systematic uncertainties, each measurement serves as a cross-check of the others.

The final state of the process used in this measurement, $\bar{t}t \to \tau + \text{jets}$, includes one top quark decaying as $t \to Wb \to \tau \nu \tau b$, while the other decays as $t \to Wb \to qq' b$, leading to the final-state topology of one $\tau$ lepton, an imbalance of momentum in the plane transverse to the beam axis ($E_T^{\text{miss}}$), and four quark jets with two of these being $b$-quark jets.

The decay $t \to \tau \nu \tau b$ provides a unique system in which to investigate the couplings of the third-generation fermions—the top and bottom quarks, the $\tau$ lepton, and the $\tau$ neutrino $\nu_\tau$—in a single process. In the framework of the Standard Model (SM), the branching ratio (BR) of the top quark decaying to a $W$ boson and a $b$ quark is approximately 100%. Hence, the final state is determined by the SM BRs of the $W$ boson, which are well measured [9]. In the SM, electroweak symmetry-breaking introduces mass- and flavor-dependent couplings. Since the top quark is the most massive quark and the $\tau$ lepton the most massive lepton, these fermions along with the $b$ quark have the largest Yukawa couplings to the Higgs boson and, hence, could lead to non-SM mass- or flavor-dependent couplings that can change the top-quark decay rate into final states with $\tau$ leptons. Therefore, any observed deviation in the BR of $t \to \tau \nu \tau b$ from that predicted by the SM would be an indication of non-SM physics. For example, in type-2 two-Higgs-doublet models (2HDM) [10], such as required by the minimal supersymmetric Standard Model [11], the top quark can have a significant BR to a charged Higgs boson ($H^\pm$) and a $b$ quark if $m_{H^\pm} < m_{\text{top}} - m_b$. For large values of $\tan \beta$, the ratio of the vacuum expectation values of the two Higgs doublets, the charged Higgs boson preferentially decays to $\tau \nu_\tau$. This thereby increases the BR of $t \to \tau \nu_\tau b$...
The 2HDM can also produce an excess of $t \rightarrow \tau + X$ decays if flavor-changing neutral couplings are allowed as in type-3 models [15,16]. For example, this allows decays if flavor-changing neutral couplings are allowed as and if the Higgs boson decays as $10$.

This article presents an analysis using the ATLAS detector [20] at the LHC covers nearly the entire solid angle around the collision point. It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer incorporating three large superconducting toroid magnets. The inner detector (ID) is immersed in a 2 T axial magnetic field and provides charged-particle tracking in the range $|\eta| < 2.5$, where $\eta$ is the pseudorapidity of the particle.\(^1\)

The high-granularity silicon pixel detector covers the interaction region and typically provides three position measurements per track. It is followed by the silicon microstrip tracker, which usually provides four two-dimensional measurement points per track. These silicon detectors are complemented by the transition radiation tracker, which enables radially extended track reconstruction up to $|\eta| = 2.0$. The transition radiation tracker also provides electron identification information based on the fraction of hits above a higher energy-deposition threshold corresponding to transition radiation.

The transition radiation tracker also provides electron identification information based on the fraction of hits above a higher energy-deposition threshold corresponding to transition radiation.

The calorimeter system covers the pseudorapidity range $|\eta| < 4.9$. Within the region $|\eta| < 3.2$, electromagnetic calorimetry is provided by barrel and endcap high-granularity lead/liquid-argon (LAr) electromagnetic calorimeters, with an additional thin LAr presampler covering $|\eta| < 1.8$ to correct for energy loss in material upstream of the calorimeters. Hadronic calorimetry is provided by the steel/scintillator-tile calorimeter, segmented into three barrel structures within $|\eta| < 1.7$, and two copper/LAr hadronic endcap calorimeters. The solid angle coverage is completed with forward copper/LAr and tungsten/LAr calorimeter modules optimized for electromagnetic and hadronic measurements, respectively.

The solid angle coverage is completed with forward copper/LAr and tungsten/LAr calorimeter modules optimized for electromagnetic and hadronic measurements, respectively.

The muon spectrometer comprises separate trigger and high-precision tracking chambers measuring the deflection of muons in a magnetic field generated by superconducting air-core toroids. The precision chamber system covers the region $|\eta| < 2.7$ with three layers of monitored drift tubes, complemented by cathode strip chambers in the innermost layer of the forward region, where the background is highest. The muon trigger system covers the range $|\eta| < 2.4$ with resistive plate chambers in the barrel, and thin gap chambers in the end-cap regions.

A three-level trigger system is used to select interesting events [21]. The Level-1 trigger is implemented in hardware and uses a subset of detector information to reduce the event rate to a design value of at most 75 kHz. This is followed by two software-based trigger levels that together reduce the event rate to about 400 Hz.

The $pp$ collision data sample used in this measurement was collected with the ATLAS detector at the LHC and corresponds to the full 20.2 fb$^{-1}$ of integrated luminosity collected at this energy with the requirement of stable beam conditions and an operational detector.

In order to estimate the effects of detector resolution and acceptance on signal and background, and to estimate the backgrounds, a full GEANT4-based detector simulation is utilized [22,23]. In addition, to estimate the modeling uncertainties of the various physics processes in an efficient manner, a detector simulation using parameterized calorimeter showers is also used [24]. To account for an average of 20.7 interactions per bunch crossing, $pp$ interactions are generated using PYTHIA v8.165 [25,26] and overlaid on the signal and background Monte Carlo (MC) simulation samples in accordance with the average observed number of interactions per bunch crossing. All simulated samples are reconstructed and analyzed with the same algorithms.
and techniques as for the recorded \( pp \) collision data. Only events with at least one charged lepton (\( e, \mu, \tau \)) in the final state are generated.

To estimate the acceptance of the event selection for \( \bar{t}t \) events, several MC samples are generated with the top-quark mass set to \( m_{\text{top}} = 172.5 \) GeV. The nominal sample is generated using the next-to-leading-order (NLO) matrix element (ME) event generator POWHEG-BOX [27–30] with the CT10 [31] NLO parton distribution functions (PDF).

The output of POWHEG-BOX is then processed by PYTHIA v6.426 [33] to regulate high-\( p_T \) tunes referred to as the Perugia 2011C tune [33]. To regulate high-\( p_T \) radiation in POWHEG-BOX and provide ME/PS matching, the resummation damping factor \( h_{\text{damp}} \) is set to \( m_{\text{top}} \) [34]. The \( \bar{t}t \) sample is normalized using the theoretical production cross section, which for \( pp \) collisions at \( \sqrt{s} = 8 \) TeV is \( \sigma_{\bar{t}t} = 253^{+13}_{-15} \) pb assuming a top-quark mass of 172.5 GeV. It has been calculated at next-to-next-to-leading order (NNLO) in \( \alpha_s \) including resummation of next-to-next-to-leading logarithmic (NNLL) soft gluon terms with top++2.0 [35–41]. The systematic uncertainty in the cross section due to the uncertainties in the PDF and \( \alpha_s \) is calculated using the PDF4LHC prescription [42] with the MSTW2008 68% CL NNLO [43,44], CT10 NNLO [31,45], and NNPDF2.3 five flavor number [46] PDF sets and added in quadrature to the uncertainties due to the renormalization and factorization scales.

Systematic uncertainties associated with the \( \bar{t}t \) modeling are evaluated using alternative sets of simulated events that are compared to the nominal sample, with the nominal and alternative sets processed using the parameterized detector simulation [44]. Since the choice of the ME event generator can affect the estimate of the acceptance, the ME event generator MC@NLO v4.01 [47] and the PS/UE simulator HERWIG v6.520 [48], with JIMMY v4.31 [49] is compared to the POWHEG-BOX [29] event generator where the PS is simulated by HERWIG+JIMMY. The effect of the PS and hadronization models on the acceptance is investigated by comparing the POWHEG+PYTHIA event generator with \( h_{\text{damp}} = \infty \) to the POWHEG+HERWIG event generator. Finally, the effect of initial- and final-state radiation (ISR and FSR) is estimated using two \( \bar{t}t \) samples generated in the same manner as the nominal sample, but with the renormalization and factorization scales multiplied by 2.0 (0.5), the regularization parameter \( h_{\text{damp}} \) set to \( m_{\text{top}} (2m_{\text{top}}) \), and using the Perugia 2012 radLo (radHi) UE tune, giving less (more) radiation. Table I summarizes the samples used to calculate the systematic uncertainties for the \( \bar{t}t \) process.

A variety of MC event generators are used to simulate the backgrounds containing charged leptons in the final state, which are summarized in Table II. Vector-boson production with additional jets (\( pp \rightarrow V + \text{jets} \), with \( V = W, Z \) and two to seven jets) is simulated using the LO parton-level ME event generator ALPGEN [50] with the PS/UE generated by PYTHIA v6.426, as for the nominal \( \bar{t}t \) samples. In order to avoid double counting, final states generated by the LO parton-level event generator ALPGEN and the parton-level shower evolution of PYTHIA, the MLM matching algorithm is used [51]. The matching algorithm is applied inclusively to the \( V + 5 \) light-parton events and exclusively to the other events. Associated production of vector bosons with heavy-flavor partons (\( V + c + \) jets, \( V + c\bar{c} + \) jets, \( V + b\bar{b} + \) jets) is simulated separately. Inclusive \( V + \) jets samples are formed by combining the light- and heavy-quark samples according to their respective cross section. An overlap removal scheme is used to avoid double counting the contribution of additional heavy flavor partons. The cross sections used to normalize the samples are calculated at NNLO [52,53].

Electroweak production of the top quark (single-top) is simulated using POWHEG-BOX [54] and PYTHIA v6.426 with the CT10 PDF set. The MC sample for the \( t \)-channel process is normalized using the NNLO calculation in Ref. [55] while the \( s \)-channel sample is normalized with

decaying into \( \tau \) leptons that cover the kinematic range expected in data and a background sample enriched in dijet events from data [64]. Three categories of discriminating variables are used. The first category comprises those variables that apply to all candidates. These are associated with the jet shape in both the tracking system and calorimeter. The second category are those variables that apply only to the single-prong \( \tau \) lepton decays. These include the impact parameter significance and the number of tracks in an isolation region \((0.2 < \Delta R < 0.4)\) around the jet axis. The third and final category are those that apply to the three-prong \( \tau \) lepton decays. These variables include the decay length significance in the transverse plane, the invariant mass of the reconstructed tracks, and the maximum track separation \((\Delta R)\) from the jet axis. An additional set of variables is used for those \( \tau_{\text{had}} \) containing \( \pi^0 \) mesons. These include the number of \( \pi^0 \) mesons, the invariant mass of the tracks plus \( \pi^0 \) mesons, and the ratio of track plus \( \pi^0 \) to the calorimeter energy only measurement. Furthermore, any jet that satisfies \( \Delta R < 0.2 \) of a \( \tau_{\text{had}} \) is removed. In addition, a BDT that includes discriminating variables against electrons is trained to reduce the electron contamination for the \( \tau_{1\text{-prong}} \) candidates. Low \( p_T \) muons that stop in the calorimeter and overlap with energy deposits from other sources can mimic a \( \tau_{\text{had}} \). These are characterized by a large fraction of energy deposited in the electromagnetic calorimeter and a small ratio of track-\( p_T \) to calorimeter-\( E_T \). Muons that produce large energy deposits in the calorimeter can also be misidentified as a \( \tau_{\text{had}} \). These are characterized by a small fraction of energy in the electromagnetic calorimeter and a large track-\( p_T \) to calorimeter-\( E_T \) ratio. Strict selection requirements based on the two variables described are applied to avoid muons being misidentified as \( \tau_{\text{had}} \). In addition, the reconstructed four-vector of the \( \tau_{\text{had}} \) candidate is not corrected for the unobserved neutrino kinematics.

Since undetected neutrinos occur in the final state, a momentum imbalance in the transverse plane is expected. The missing transverse momentum \( (E_T^{\text{miss}}) \) is calculated as the negative of the vector sum of the transverse momentum of all reconstructed objects and of the calorimeter energy deposits not associated to any reconstructed object after the appropriate energy corrections have been applied [65].

V. EVENT SELECTION

Events are selected that satisfy the \( E_T^{\text{miss}} > 80 \) GeV trigger with an offline reconstruction requirement of \( E_T^{\text{miss}} > 150 \) GeV. This is the point at which the trigger has almost reached full efficiency. Furthermore, events are required to contain a hard collision primary vertex with at least four associated charged particle tracks of \( p_T > 0.4 \) GeV. If there are multiple primary vertices in an event, the one with the largest sum of track \( p_T \) is selected. To reduce contamination from events with
\( t\bar{t} \to e(\mu) + \text{jets} \), an event is rejected if it contains an electron (\( p_T^e > 25 \text{ GeV} \)) [66] or a muon (\( p_T^\mu > 20 \text{ GeV} \)) candidate [67], each with \(|\eta| < 2.5\) that satisfy the corresponding selection in the ATLAS \( t\bar{t} \to e(\mu) + \text{jets} \) cross-section measurement [2]. The event must also contain at least two jets with \( E_T > 25 \text{ GeV} \) and \(|\eta| < 2.5\). In addition, at least two of the jets in the event must be identified as \( b\)-quark jets using a \( b\)-tagging requirement with 70\% efficiency. Each event is also required to contain at least one \( t\bar{t} \) that decays to either one or three charged particles with \( E_T > 20 \text{ GeV} \) and \(|\eta| < 2.5\) and a \( \tau \) lepton identification requirement that discriminates against quark and gluon initiated jets such that the efficiency is 40\% for single-prong and 35\% for three-prong \( t\bar{t} \) with a rejection factor between 100 and 1000 depending on the \( p_T \) and \( \eta \) for each. This identification requirement defines the standard \( t\bar{t} \) selection. Since the background for \( t\bar{t} \) and three-prong identification is different, the two samples are analyzed separately with the \( t\bar{t} \) (three-prong) analysis requiring one or more \( t\bar{t} \) (three-prong) only. In each case, the highest-\( p_T \) \( t\bar{t} \) is used with less than 1\% of events containing more than a single \( t\bar{t} \). The combined result is produced by requiring an event to contain either one or more \( t\bar{t} \) or \( t\bar{t} \) and selecting the highest-\( p_T \) \( t\bar{t} \) in the event. In order to preferentially select events where the \( t\bar{t} \) and \( E_T^{miss} \) originate from \( W\)-boson decays, the transverse mass is required to satisfy \( m_T < 90 \text{ GeV} \), where \( m_T \) comprises the \( t\bar{t} \) with the largest \( p_T \) and the value of the \( E_T^{miss} \) of the event. The event of the transverse mass is defined as \( m_T^2 = p_T^{t\bar{t}} E_T^{miss} [1 - \cos \Delta \phi(t\bar{t}, E_T^{miss})] \) and \( \Delta \phi(t\bar{t}, E_T^{miss}) \) is the azimuthal angle between the direction of the \( t\bar{t} \) and the \( E_T^{miss} \) of the event.

VI. BACKGROUND ESTIMATION

To determine the number of \( pp \to t\bar{t} + X \to t\bar{t} + \text{jets} \) events in the data sample, estimates of the various backgrounds are subtracted. These originate from two sources: the backgrounds with real \( t\bar{t} \) and those with misidentified \( t\bar{t} \) in the final state. The backgrounds containing real \( t\bar{t} \) in the final state include single-top-quark events, \( V + \text{jets} \) events, and diboson events. These backgrounds are estimated in simulation and normalized using their theoretical cross sections as discussed in Sec. III. The misidentified (fake) \( t\bar{t} \) background consists of events from processes where a charged lepton (\( e^\pm \) and \( \mu^\pm \)) is misidentified as a \( t\bar{t} \) and multijet events that have a mismeasured \( E_T^{miss} \) and a quark- or gluon-initiated jet that is misidentified as a \( t\bar{t} \).

Misidentification of electrons and muons as \( t\bar{t} \) is significantly reduced by applying the selection criteria discussed in Sec. IV. The \( t\bar{t} \) background where an electron or a muon is misidentified as a \( t\bar{t} \) is simulated in POWHEG+PYTHIA and normalized using the theoretical \( t\bar{t} \) production cross section. The contribution from other processes where an electron or a muon is misidentified as a \( t\bar{t} \) is found to be negligible.

To estimate the fraction of events in which a jet is misidentified as a \( t\bar{t} \), a data-based method is used where this fraction is evaluated in a control sample that is divided into two components: one with the standard \( t\bar{t} \) selection and the other with an inverted \( t\bar{t} \) selection. The transfer factor is the ratio of the number of events with misidentified \( t\bar{t} \) in the nominal sample to that in the inverted sample. This transfer factor, which is referred as the fake-factor FF, is then applied to the signal sample with the inverted \( t\bar{t} \) selection, which yields the fraction of misidentified \( t\bar{t} \) in the signal sample with the nominal \( t\bar{t} \) selection. The inverted \( t\bar{t} \) selection is determined such that the fraction of quark- and gluon-jets that can be misidentified as a \( t\bar{t} \) is similar to the fractions when the standard \( t\bar{t} \) selection is applied, as derived from MC simulation. All other requirements are the same as for the signal sample. This technique, known as the fake-factor method, has been used in previous ATLAS measurements [68].

To ensure a large fraction of events with jets misidentified as \( t\bar{t} \), the control sample is required to satisfy a muon trigger with only a single reconstructed muon satisfying the requirement \( p_T > 25 \text{ GeV} \) and \(|\eta| < 2.5\). In addition, each event is also required to satisfy the following criteria: (1) contain a primary vertex with at least four associated tracks, (2) contain at least two jets and no jet in the event satisfying the \( b\)-jet criteria, and (3) contain a single \( t\bar{t} \) satisfying selection criteria that are less restrictive than the nominal. The control sample is then separated into a component satisfying the standard \( t\bar{t} \) identification and a second component that satisfies the inverted identification criteria. This set of selections ensures that the control sample is enriched with misidentified \( t\bar{t} \) for both the standard and the inverted \( t\bar{t} \) identification criteria. The number of data events selected with the standard \( t\bar{t} \) identification is 28 397, where the contribution from real \( t\bar{t} \) is 38\% as estimated from simulation. For the inverted \( t\bar{t} \) identification, the number of data events is 84 975 with a contribution of 9\% from real \( t\bar{t} \). The transfer factor is calculated in bins of \( p_T \) and \( \eta \) after the real \( t\bar{t} \) contributions are subtracted. The FF averaged over the full kinematic range of this measurement has a value of 0.23 ± 0.01(stat).

To extract the number of misidentified \( t\bar{t} \) in the signal sample, the nominal selection with the inverted \( t\bar{t} \) identification is applied to data. To correct for real \( t\bar{t} \) in this sample, an estimate of the number of real \( t\bar{t} \) is derived from simulation and subtracted from this sample. Next, the derived FF is applied to the resulting data sample according to the \( p_T \) and \( \eta \) of the selected \( t\bar{t} \) taking into account the number of \( t\bar{t} \) in the event. This yields the number of misidentified \( t\bar{t} \) in the signal sample.

In order to validate this procedure, the derived FF is applied to a data set that does not overlap with the nominal
or at least one \( \tau \).

An additional validation sample that is dominated by real data and the background estimate is seen in all categories.

The transverse mass of the \( \tau \) is constructed from the following six categories: (1) two inclusive jets; (2) three inclusive jets; (3) four inclusive jets; with each listed jet multiplicity containing either zero \( b \)-quark jets by dividing the sample into the following six categories: (1) two inclusive jets; (2) three inclusive jets; (3) four inclusive jets; with each listed jet multiplicity containing either zero \( b \)-quark jets or at least one \( b \)-quark jet. Good agreement between the data and the background estimate is seen in all categories.

An additional validation sample that is dominated by real \( \tau \) is formed by selecting \( Z \rightarrow \tau^+\tau^- \) events, where one \( \tau \) lepton decays to a final state containing a \( \mu \) and the other containing hadrons. This sample is selected by requiring: (1) \( \cos \Delta \phi(\mu, E_T^{\text{miss}}) + \cos \Delta \phi(\tau, E_T^{\text{miss}}) > -0.15 \); (2) \( \Delta \phi(\mu, \tau) > 2.4 \); (3) \( m_\tau^\mu < 50 \text{ GeV} \), where \( m_\tau^\mu \) is the transverse mass of the \( \mu \) and the \( E_T^{\text{miss}} \) of the event; (4) \( 42 < m(\mu, \tau) < 82 \text{ GeV} \), the invariant mass of the \( \mu-\tau \) system; (5) \( 25 < p_T^\tau < 40 \text{ GeV} \). Figure 1 shows an example of a comparison between the data and the prediction for regions dominated by misidentified and real \( \tau \).

**VII. EXTRACTION OF THE \( \bar{t}t \) PRODUCTION CROSS SECTION**

In order to determine the \( \bar{t}t \) cross section, the estimated background, given in Table III, is subtracted from the number of recorded events after the event selection is applied, then normalized to the integrated luminosity \( \int \mathcal{L}(t)dt \) and corrected by the efficiency \( e_{\bar{t}t} = 5 \times 10^{-4} \), which is calculated from the fraction of events satisfying the geometric, kinematic, trigger, and object identification selection, and the effects of the detector reconstruction. Therefore, the cross section is given as

\[
\sigma(pp \rightarrow \bar{t}t + X) = \frac{N_{\text{data}} - N_{\text{bkg}}}{BR \times e_{\bar{t}t} \times \int \mathcal{L}(t)dt}.
\]

Furthermore, since the calculated efficiency corresponds to all \( \bar{t}t \) final states containing leptons only, the BR(\( \bar{t}t \rightarrow e + X \)) = 0.54 is used. The number of background events \( N_{\text{bkg}} \) comprises backgrounds with real \( \tau \) that are estimated from the simulated samples and events containing a misidentified \( \tau \) that is estimated using the fake-factor method discussed in Sec. VI. As also discussed in Sec. VI, to estimate the number of misidentified \( \tau \), the real \( \tau \) contribution must be subtracted including those from \( \mu \) events. Since this would require the use of the \( \bar{t}t \) cross section, which is the quantity being measured, Eq. (1) is reformulated as

\[
\sigma(pp \rightarrow \bar{t}t + X) = \frac{N_{\text{data}} - N_{\text{bkg-non}\bar{t}t}}{BR \times (e_{\bar{t}t} - e_{\bar{t}t-m\mu}) \times \int \mathcal{L}(t)dt},
\]

where \( N_{\text{bkg-non}\bar{t}t} \) represents the backgrounds estimated from the simulated samples and the misidentified \( \tau \) component.
estimated using the fake-factor method but excludes the subtraction of the $\bar{t}\bar{t}$ component. The efficiency $\epsilon_{\bar{t}\bar{t},TT} = 7 \times 10^{-5}$ represents $\bar{t}\bar{t}$ events satisfying the inverted $\tau_{\text{had}}$ identification.

**VIII. SYSTEMATIC UNCERTAINTIES**

Systematic uncertainties are grouped into those pertaining to object identification along with its energy and momentum measurement, theoretical modeling, background evaluation, and the luminosity. The systematic uncertainties are evaluated by performing a variation of each parameter related to the associated quantity and propagating the overall uncertainty to the cross section assuming that the individual uncertainties are uncorrelated. The procedures and results for the individual quantities considered are summarized below. The systematic uncertainties are calculated for the $\tau_{1\text{-prong}}$, $\tau_{3\text{-prong}}$, and the combined $\tau_{\text{had}}$ analyses separately, with the resulting values given in Table IV.

The uncertainty in the cross section due to jet reconstruction is split into three components: the jet energy scale, its energy resolution, and its reconstruction efficiency. The uncertainty from the jet energy scale is calculated by varying the correction factors by one correction factor [63]. This uncertainty is propagated to the cross section by varying the correction factors by one standard deviation.

The systematic uncertainty of $E_{\text{T}}^{\text{miss}}$ is evaluated along with the systematic uncertainty of the associated energy and momentum of the reconstructed objects as discussed above. Not included in that calculation are the contributions from low-$p_T$ jets and energy deposits in the calorimeter cells not associated with a reconstructed object. This source of uncertainty is evaluated using the difference between the $E_{\text{T}}^{\text{miss}}$ calculation.

In the nominal analysis, the $b$-tagging efficiency in simulation is corrected to agree with data by using $p_T$- and $\eta$-dependent correction factors. The uncertainty in the correction factors is obtained independently for $b$-jets, $c$-jets, and light-flavor jets assuming that they are uncorrelated. The uncertainties of the inefficiency correction factors that are applied when a jet is not tagged are treated as fully anticorrelated with the corresponding efficiency correction factor [63]. This uncertainty is propagated to the cross section by varying the correction factors by one standard deviation with respect to the central value.

As in $b$-tagging, correction factors are used to correct for the difference in the $\tau_{\text{had}}$-tagging efficiency and the $\tau_{\text{had}}$ electron veto efficiency between data and simulation. The uncertainties in the correction factors depend on $p_T$, $\eta$, and the $\tau_{\text{had}}$ identification criteria. In addition, the $\tau_{\text{had}}$ energy scale can affect the final result due to the $\tau_{\text{had}}$ $p_T$ requirement. The energy of the $\tau_{\text{had}}$ is calculated using MC simulation to correct the observed energy to the true energy scale [64]. Additional small data-based corrections are then applied. The uncertainties due to each of these effects are propagated to the cross section by varying the correction factors by one standard deviation.

**TABLE IV.** Relative percent uncertainties in the measured cross section in the $\tau_{1\text{-prong}}$, $\tau_{3\text{-prong}}$ and combined $\tau_{1\text{-prong}}$ and $\tau_{3\text{-prong}}$ ($\tau_{\text{had}}$) final states. In the $\tau_{1\text{-prong}}$ ($\tau_{3\text{-prong}}$) analysis, all $\tau_{\text{had}}$ in the event are required to be $\tau_{1\text{-prong}}$ ($\tau_{3\text{-prong}}$). For the combined analysis, the $\tau_{\text{had}}$ in an event could be of either type.

data and simulated $Z \to \mu^+\mu^-$ events containing no jets, which is similar to the procedure used in Ref. [65].

The systematic uncertainty due to $t\bar{t}$ modeling is split into two components. The first is that associated with the choice of ME event generator and PS/UE event simulation. The uncertainty associated with the choice of ME event generator is estimated by comparing the acceptance from the MC@NLO event generator with that from the POWHEG-BOX event generator. Events from both event generators are processed through the PS/UE simulator HERWIG+JIMMY. The uncertainty due to the PS on the acceptance is estimated by comparing the POWHEG+PYTHIA event generator to the POWHEG+HERWIG event generator. The second component of the modeling uncertainty corresponds to the effect of ISR and FSR on the event selection due to possible extra jets and changes in the kinematics of the final-state particles and jets. The nominal $t\bar{t}$ sample is compared to samples with variations of the renormalization and factorization scales and the regularization parameter as described in Sec. III.

The systematic uncertainties due to the various backgrounds that contain real $\tau_{\text{had}}$ are derived using the MC samples described in Sec. III and the uncertainties of the theoretical cross sections. The two largest sources of real $\tau_{\text{had}}$ backgrounds are single-top and $W +$ jets events. All other background contributions to the systematic uncertainty are negligible. For single-top, the uncertainty in the cross section of the MC sample is varied by one standard deviation and propagated to the cross section. For the $W +$ jets background, the same procedure is followed but is validated using a method based on the W-boson charge asymmetry in data as described in Refs. [70–72], which gives agreement with the estimation based on the theoretical uncertainty.

To estimate the systematic uncertainty in the number of misidentified $\tau_{\text{had}}$, the effect of variations of the main components of this analysis are examined. The main components are: (1) the MC-based background subtraction of the real $\tau_{\text{had}}$, (2) uncertainty in the flavor dependence of the FF, (3) uncertainty associated with the $\eta_{\text{pT}}$ binning of the FF. In calculating the FF, the largest contribution from real $\tau_{\text{had}}$ is from $Z +$ jets events, as the final state $Z \to \tau^+\tau^- \to \tau_{\text{had}}\mu + X$ satisfies the selection. To estimate this component of the uncertainty, the $Z +$ jets cross section is varied by ±1 standard deviation. This variation leads to an average uncertainty of 5% over the $p_{\text{T}}$-$\eta$ range for this component of the FF. The FF is calculated in a sample dominated by light-flavor jets. To estimate the systematic uncertainty of the flavor composition, the FF is also derived in a gluon-jet-dominated sample with four jets and low $E_{\text{T}}^{\text{miss}}$. Using this sample the FF is calculated and applied to the signal sample, resulting in an uncertainty of 20% in the number of misidentified $\tau_{\text{had}}$ events. Since the FF is calculated in $p_{\text{T}}$-$\eta$ bins, the bin size is also varied to estimate the uncertainty in the final result. The uncertainty in the final result is found to be approximately 5% of the calculated number of misidentified $\tau_{\text{had}}$ events.

The absolute luminosity scale is derived from beam-separation scans performed in November 2012. From the calibration of the absolute luminosity scale, the uncertainty in the total integrated luminosity is evaluated following the procedure described in Ref. [73] and is found to be 1.9%.  

FIG. 2. The distribution of the (a) $p_{\text{T}}$ of the $\tau_{\text{had}}$ having highest transverse momentum in the event and (b) the missing transverse momentum, $E_{\text{T}}^{\text{miss}}$. The observed data are compared to the predictions.

This uncertainty is then propagated to the cross-section measurements yielding a 2.3% uncertainty, which is reported independent of the other systematic uncertainties.

**IX. RESULTS AND INTERPRETATION**

The number of events observed for each $t_\text{had}$ type and for the combined analysis are reported in Table III along with the predicted number of background events. The uncertainties associated with the cross-section measurement from each of the different sources are reported in Table IV. Figure 2 shows the kinematic distributions of the predicted background and signal processes with the observed data superimposed, where the signal-to-background ratio is approximately 4:1.

The cross sections for each $t_\text{had}$ type measured separately are

\[
\sigma_{t\bar{t}}(t_1\text{prong} + \text{jets}) = 237 \pm 5(\text{stat}) \pm 26(\text{syst}) \pm 5(\text{lumi}) \text{ pb},
\]

\[
\sigma_{t\bar{t}}(t_3\text{prong} + \text{jets}) = 243 \pm 14(\text{stat}) \pm 34(\text{syst}) \pm 6(\text{lumi}) \text{ pb},
\]

and the cross section for the combined analysis is

\[
\sigma_{t\bar{t}} = 239 \pm 4(\text{stat}) \pm 28(\text{syst}) \pm 5(\text{lumi}) \text{ pb}.
\]

The combined cross section has an uncertainty of 12% and is in agreement with the previous measurements of the ATLAS Collaboration for the $e + \text{jets}$ and $\mu + \text{jets}$ final states [2]. Since the analysis is performed at a fixed top-quark mass, samples are generated at various masses to study the dependence of the measured cross section on $m_{t\bar{t}}$. The variation is found to be $(\Delta \sigma/\sigma)/\Delta m_{t\bar{t}} = -2.6\%$ GeV$^{-1}$.

In order to quantify the compatibility of this result with the SM and explore the allowed range for non-SM processes, a frequentist significance test using a background-only hypothesis is used to compare the observed number of events with the SM prediction. In this procedure, the $t\bar{t} \rightarrow \tau + X$ process is considered a background and estimated according to the SM prediction taking into account the corresponding uncertainty. This statistical analysis is also used to derive a limit in a model-independent manner on possible beyond-the-SM (BSM) physics. A confidence level for the background-only hypothesis (CL$_b$) of 0.48 corresponding to a $p$-value of 0.52 is observed, which indicates good agreement between the observed data and the SM processes. An upper limit at 95% confidence level (CL) on the number of BSM events is derived using the CL$_s$ likelihood ratio method described in Ref. [74]. The upper limit is calculated with the observed number of events, the expected background, and the background uncertainty. Dividing the upper limits on the number of BSM events by the integrated luminosity of the data sample, the resulting value can be interpreted as the upper limit on the visible BSM cross section, $\sigma_{\text{vis}} = \sigma \times \epsilon$, where $\sigma$ ($\epsilon$) is the production cross section (efficiency) for the BSM process. Table V summarizes the observed number of events, the estimated SM background yield, and the expected and observed upper limits on the event yields and on the $\sigma_{\text{vis}}$ from any BSM process. The efficiency for each SM process used to calculate this limit is reported in Table VI.

Using the same data sample as the cross-section measurement, an upper limit on the flavor changing process $t \rightarrow qH \rightarrow q\tau^+\tau^-$ is set by performing a modified analysis and then calculating a limit in a manner that is similar to that of the model-independent limit. In the modified analysis, exactly one identified $b$-jet and two $t_\text{had}$ are required. Performing the same statistical analysis for the cross-section measurement, a 95% CL observed (expected) upper limit of 0.60% (0.9%) is set on the BR$(t \rightarrow qH) \times \text{BR}(H \rightarrow \tau\tau)$. At present, this is the only analysis that can explore the channel $t \rightarrow qH \rightarrow q\tau\tau$ and, hence, is the first search using the $H \rightarrow \tau\tau$ final state. Assuming the SM BR$(H \rightarrow \tau\tau) = 6\%$, the 95% CL observed (expected) upper limit set on the BR$(t \rightarrow qH)$ is 10% (15%). A dedicated ATLAS measurement achieves a 95% CL upper limit of 0.45% on the BR$(t \rightarrow qH)$ in the combination of Higgs boson final states $H \rightarrow bb$, $H \rightarrow \gamma\gamma$ and $H \rightarrow \text{multilepton}(e, \mu)$ [75].

**X. SUMMARY**

A measurement of the $pp \rightarrow t\bar{t} + X$ cross section at $\sqrt{s} = 8$ TeV using 20.2 fb$^{-1}$ of integrated luminosity collected with the ATLAS detector has been performed.
in the $t\bar{t} \to \tau_\ell q\bar{q}' b\bar{b}$ final state using hadronic decays of the $\tau$ lepton. The cross section is measured separately for hadronic decays of the $\tau$ lepton into one or three charged particles. A single analysis using a combination of both decay modes is also performed. The cross section measured in the single analysis is $\sigma_{\text{tot}} = 239 \pm 4(\text{stat}) \pm 28(\text{syst}) \pm 5(\text{lumi}) \text{ pb}$, assuming a top-quark mass of $m_{\text{top}} = 172.5 \text{ GeV}$. The measured cross section is in agreement with the SM prediction of $253^{+13}_{-15} \text{ pb}$. A statistical analysis is performed to check the consistency of the observed number of events in data with the predicted number of events from various SM processes. Following a frequentist approach, the confidence level observed with the SM-only hypothesis is 0.48 and the calculated $p$-value is 0.52, which indicates good agreement of the SM prediction with the observed data. A model-independent upper limit on the visible cross section for any non-SM process is also calculated. The observed (expected) upper limit at 95% confidence level on the visible cross section of any non-SM processes is $22(22^{+2}_{-1}) \text{ fb}$.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. Physics Department, Lancaster University, Lancaster, United Kingdom

INFN Sezione di Lecce, Italy

Dipartimento di Matematica e Fisica, Università del Salento, Lecce, Italy

Oliver Lodge Laboratory, University of Liverpool, Liverpool, United Kingdom

Department of Experimental Particle Physics, Jožef Stefan Institute and Department of Physics, University of Ljubljana, Ljubljana, Slovenia

School of Physics and Astronomy, Queen Mary University of London, London, United Kingdom

Department of Physics, Royal Holloway University of London, Egham, United Kingdom

Department of Physics and Astronomy, University College London, London, United Kingdom

Louisiana Tech University, Ruston Los Angeles, USA

Laboratoire de Physique Nucléaire et de Hautes Energies, UPMC and Université Paris-Diderot and CNRS/IN2P3, Paris, France

Fysiska institutionen, Lunds universitet, Lund, Sweden

Departamento de Física Teorica C-15, Universidad Autonoma de Madrid, Madrid, Spain

Institut für Physik, Universität Mainz, Mainz, Germany

School of Physics and Astronomy, University of Manchester, Manchester, United Kingdom

CPPM, Aix-Marseille Université and CNRS/IN2P3, Marseille, France

Department of Physics, University of Massachusetts, Amherst Massachusetts, USA

Department of Physics, McGill University, Montreal Quebec, Canada

School of Physics, University of Melbourne, Victoria, Australia

Department of Physics, The University of Michigan, Ann Arbor Michigan, USA

Department of Physics and Astronomy, Michigan State University, East Lansing Michigan, USA

INFN Sezione di Milano, Italy

Dipartimento di Fisica, Università di Milano, Milano, Italy
Measurement of the $ar{t}t$ production cross ...
MEASUREMENT OF THE $\bar{\nu}_t$ PRODUCTION CROSS ...

PHYSICAL REVIEW D 95, 072003 (2017)

176Department of Physics, University of Wisconsin, Madison Wisconsin, USA
177Fakultät für Physik und Astronomie, Julius-Maximilians-Universität, Würzburg, Germany
178Fakultät für Mathematik und Naturwissenschaften, Fachgruppe Physik, Bergische Universität Wuppertal, Wuppertal, Germany
179Department of Physics, Yale University, New Haven Connecticut, USA
180Yerevan Physics Institute, Yerevan, Armenia
181Centre de Calcul de l’Institut National de Physique Nucléaire et de Physique des Particules (IN2P3), Villeurbanne, France

aDeceased.
bAlso at Department of Physics, King’s College London, London, United Kingdom.
cAlso at Institute of Physics, Azerbaijan Academy of Sciences, Baku, Azerbaijan.
daAlso at Novosibirsk State University, Novosibirsk, Russia.
eAlso at TRIUMF, Vancouver BC, Canada.
fAlso at Department of Physics & Astronomy, University of Louisville, Louisville, KY, USA.
gAlso at Physics Department, An-Najah National University, Nablus, Palestine.
hAlso at Department of Physics, California State University, Fresno, CA, USA.
iAlso at Department of Physics, University of Fribourg, Fribourg, Switzerland.
jAlso at Departament de Física de la Universitat Autònoma de Barcelona, Barcelona, Spain.
kAlso at Departamento de Física e Astronomia, Faculdade de Ciencias, Universidade do Porto, Portugal.
lAlso at Tomsk State University, Tomsk, Russia, Russia.
mAlso at The Collaborative Innovation Center of Quantum Matter (CICQM), Beijing, China.
nAlso at Universita di Napoli Parthenope, Napoli, Italy.
oAlso at Institute of Particle Physics (IPP), Canada.
pAlso at Horia Hulubei National Institute of Physics and Nuclear Engineering, Bucharest, Romania.
qAlso at Department of Physics, St. Petersburg State Polytechnical University, St. Petersburg, Russia.
rAlso at Department of Physics, The University of Michigan, Ann Arbor MI, USA.
sAlso at Centre for High Performance Computing, CSIR Campus, Rosebank, Cape Town, South Africa.
tAlso at Louisiana Tech University, Ruston LA, USA.
uAlso at Institutio Catalana de Recerca i Estudis Avancats, ICREA, Barcelona, Spain.
wAlso at Graduate School of Science, Osaka University, Osaka, Japan.
xAlso at Fakultät für Mathematik und Physik, Albert-Ludwigs-Universität, Freiburg, Germany.
yAlso at Institute for Mathematics, Astrophysics and Particle Physics, Radboud University Nijmegen/Nikhef, Nijmegen, Netherlands.
zAlso at Department of Physics, The University of Texas at Austin, Austin TX, USA.
aAlso at Institute of Theoretical Physics, Ilia State University, Tbilisi, Georgia.
bAlso at CERN, Geneva, Switzerland.
cAlso at Georgian Technical University (GTU),Tbilisi, Georgia.
dAlso at Ochadai Academic Production, Ochanomizu University, Tokyo, Japan.
eAlso at Manhattan College, New York NY, USA.
fAlso at Academia Sinica Grid Computing, Institute of Physics, Academia Sinica, Taipei, Taiwan.
gAlso at School of Physics, Shandong University, Shandong, China.
hAlso at Departamento de Física Teórica y del Cosmos and CAFPE, Universidad de Granada, Granada (Spain), Portugal.
iAlso at Department of Physics, California State University, Sacramento CA, USA.
jAlso at Moscow Institute of Physics and Technology State University, Dolgoprudny, Russia.
kAlso at Departement de Physique Nucleaire et Corpusculaire, Université de Genève, Geneva, Switzerland.
lAlso at Eotvos Lorand University, Budapest, Hungary.
mAlso at Departments of Physics & Astronomy and Chemistry, Stony Brook University, Stony Brook NY, USA.
Also at International School for Advanced Studies (SISSA), Trieste, Italy.
Also at Department of Physics and Astronomy, University of South Carolina, Columbia SC, USA.
Also at Institut de Fisica d’Altes Energies (IFAE), The Barcelona Institute of Science and Technology, Barcelona, Spain.
Also at School of Physics, Sun Yat-sen University, Guangzhou, China.
Also at Institute for Nuclear Research and Nuclear Energy (INRNE) of the Bulgarian Academy of Sciences, Sofia, Bulgaria.
Also at Faculty of Physics, M.V.Lomonosov Moscow State University, Moscow, Russia.
Also at Institute of Physics, Academia Sinica, Taipei, Taiwan.
Also at National Research Nuclear University MEPhI, Moscow, Russia.
Also at Department of Physics, Stanford University, Stanford CA, USA.
Also at Institute for Particle and Nuclear Physics, Wigner Research Centre for Physics, Budapest, Hungary.
Also at Giresun University, Faculty of Engineering, Turkey.
Also at Flensburg University of Applied Sciences, Flensburg, Germany.
Also at CPPM, Aix-Marseille Université and CNRS/IN2P3, Marseille, France.

Also at University of Malaya, Department of Physics, Kuala Lumpur, Malaysia.

Also at LAL, Univ. Paris-Sud, CNRS/IN2P3, Université Paris-Saclay, Orsay, France.
