I. INTRODUCTION

The first observing run (O1) of the Advanced Laser Interferometer Gravitational-Wave Observatory (LIGO) detectors [1] took place from September 12, 2015 to January 19, 2016. During this period, there were a total of 51.5 days of coincident analysis time between the two detectors, located in Hanford, Washington (H1), and Livingston, Louisiana (L1). This resulted in the detection of gravitational-wave (GW) signals from the coalescence of two binary black hole (BBH) systems with high statistical significance, GW150914 [2] and GW151226 [3], and a third lower-significance candidate, LVT151012 [4], which is also likely to be a BBH coalescence [5].

In all three cases, the estimated premerger individual source-frame masses, \((36.2^{+5.2}_{-3.8}, 29.1^{+3.7}_{-4.4})\, M_\odot\), \((14.2^{+8.3}_{-3.7}, 7.5^{+2.3}_{-3.5})\, M_\odot\), and \((23^{+18}_{-6}, 13^{+4}_{-2})\, M_\odot\), respectively [5,6], are consistent with stellar evolutionary scenarios [7]. These systems were observed at relatively low redshifts, \(z = 0.09^{+0.03}_{-0.04}, 0.09^{+0.03}_{-0.04}\), and \(0.20^{+0.09}_{-0.09}\), respectively. If relatively heavy black hole remnants, similar to those already observed by Advanced LIGO, exist within dense globular cluster (GCs), further hierarchical merging of these objects could be a natural formation mechanism for intermediate mass black holes (IMBHs) [9]. IMBHs are normally defined as black holes with masses in the range \(10^2 \leq M_*/M_\odot \leq 10^5\); in this paper, we consider any BBH with a total mass above \(10^2\, M_\odot\) and mass ratio of \(0.1 \leq q \leq 1\) to be an IMBH binary (IMBHB).

It is possible that there will be numerous BBH detections in the next few years of GW astronomy [5,10,11]. In the near future, we should be able to place stringent astrophysical constraints on the formation and evolution of stellar-mass black holes. In addition to surveying stellar-mass black holes, we will also be able to investigate the astrophysics of IMBHs.

If they are found to exist, IMBHB mergers would be the LIGO-Virgo sources that emit the most gravitational-wave energy. Given an estimate of the power spectral density of a detector [12], and assuming a matched-filter single-detector signal-to-noise ratio (SNR) threshold of 8, in Fig. 1 we plot the horizon distance (the distance to which we can detect an optimally located and oriented source) as a function of source-frame total mass. As Fig. 1 displays, the O1 sensitivity for IMBHBs constitutes a factor of \(\approx 6\) improvement in peak horizon distance (\(\approx 200\) in search volume) as compared to the sensitivity achieved between 2009 and 2010, during the sixth and final science run (S6) of initial LIGO [13]. However, the matched-filter SNR is only an optimal detection statistic in stationary, Gaussian noise. Since LIGO data are known to contain nonstationary noise [14], this figure is useful primarily as an approximate upper bound on the reach of a modeled search for IMBHBs.

In this paper, we report on the search for IMBHBs during O1. In previous IMBHB searches using LIGO-Virgo data taken in 2005–2010 [13,16], an unmodeled transient search and a modeled matched-filter search using only the ringdown part of the waveform were separately employed to set distinct upper limits on the merger rates of IMBHBs. For this study, two distinct search pipelines were also used: a..
matched-filter search algorithm, GstLAL [17–19], that uses inspiral–merger–ringdown waveform templates [4,5] which are cross-correlated with the data, and an unmodeled transient search algorithm, coherent WaveBurst (cWB)

TABLE I. Results of our analysis for IMBHB systems with (source-frame) component masses $m_{1,2}$ and spins $\chi_{1,2}$ parallel to the orbital angular momentum. For each set of parameters, we report the 90% confidence combined upper limit on the rate density $R_{90\%}$ and the combined- and single-pipeline sensitive distance $D_{90\%}$. Uncertainty in the detectors’ amplitude calibration introduces an $\approx 18\%$ uncertainty in the rates and an $\approx 6\%$ uncertainty in the sensitive distance.

$$

For O1, a new search was inaugurated, in which both modeled and unmodeled analyses, specifically tuned to search for IMBHBs, were combined to form a single search. The modeled analysis employs a matched filter, which yields the optimal detection efficiency for signals of known form in stationary, Gaussian noise [23] and thus requires a sufficiently accurate signal waveform model for use as a template. The unmodeled transient analysis, by contrast, can identify burstlike signals which do not correspond to any currently available waveform model. IMBHB signals, as a consequence of their sources’ high mass, have relatively few cycles in the LIGO frequency band; therefore, the IMBHB search benefits from the combination of the two complementary analysis techniques.

A. Modeled analysis

The GstLAL pipeline, which is a matched-filter search algorithm for GWs from compact binary coalescences [17–19], was used in its offline mode to analyze the entirety of O1 [4,5]. The GstLAL IMBHB analysis is based on a discrete bank of GW templates constructed over a total mass between 50 $M_\odot$ and 600 $M_\odot$ in the detector frame, with mass ratios less extreme than 1:10, and with dimensionless spin $\chi_{1,2}$ between $-0.99$ and 0.99, where positive values are aligned with the orbital angular momentum of the system and negative values are antialigned. The templates used in this search are a reduced-order model of a double aligned-spin effective-one-body waveform [24,25]. As a consequence of the noise characteristics at low frequencies [12], GstLAL began its analysis at a frequency of 15 Hz.

In this analysis, the data are filtered through a singular-value decomposition of the template bank, and the matched-filter SNR time series for each template in the bank is reconstructed from the filtered output of the basis templates [19]. Maxima in the SNR, called triggers, are
identified, and corresponding values of a signal consistency test, which is a comparison of the SNR time series for the data to the SNR time series expected from a real signal, are computed. Triggers found in one detector that are not coincident with triggers in another detector are assumed to be nonastrophysical and are used to estimate the probability distribution of noise events in each detector. Coincident triggers are considered GW candidates and are ranked against each other via a likelihood ratio, which compares the probability that each is a signal to the probability that each is noise\(^{19}\). Finally, a coincident trigger is assigned a \(p\)-value \(^{19}\), which is the probability of finding a noise fluctuation with such likelihood ratio or higher under the hypothesis that the data contain no GW signals.\(^2\)

For validation, another independent matched-filter search algorithm, PyCBC \(^{27,28}\), was also run over the same GW parameter space using a spin-aligned frequency-domain phenomenological waveform model \(^{29,30}\) as templates. PyCBC uses a different SNR-based ranking statistic \(^{4,27,28,31}\). These two independent matched-filter algorithms find consistent results over the IMBH parameter space, which increases our confidence in their reliability and robustness.

The three most significant events from the GstLAL matched-filter analysis correspond to GW150914, LVT151012, and GW151226, which have already been reported \(^{2–6}\). Since parameter-estimation studies have placed these events outside of the IMBH mass range \(^{4–6,32}\), we have removed these triggers from our analysis. We discuss the production of our overall IMBHB results in Sec. II C.

The bank of waveform templates used by the GstLAL IMBHB analysis notably overlaps with the O1 stellar-mass BBH search \(^{4,5}\) between \(M = 50 \, M_\odot \) and \(100 \, M_\odot \). It was therefore expected that this new analysis would find GW150914 and LVT151012 as two of its most significant events, since the masses of these two signals have posterior support in this range \(^{4–6}\). Additionally, GW151226 being the third most significant event in this analysis demonstrates the robustness of modeled analyses to identify signals even outside of their covered parameter spaces.

This is the first modeled analysis that includes the inspiral, merger, and ringdown portions of the compact binary coalescence waveform to extend above \(M = 100 \, M_\odot \) and into the IMBHB parameter space. Even though IMBHB mergers potentially have large values of SNR, detecting them with this analysis can be difficult. Signal consistency checks are often inefficient at distinguishing true signals from background events. This problem is caused primarily by the short duration of signals produced by high-mass systems, especially those with antialigned spin configurations. Continuing to pursue improvements in IMBHB search methods will undoubtedly improve the sensitivity of the analysis.

### B. Unmodeled analysis

The unmodeled analysis was conducted with cWB, the data-analysis algorithm used for previous LIGO-Virgo unmodeled IMBHB searches \(^{13,33}\). More recently, this algorithm has been used extensively on O1 data \(^{22}\).

---

\(^{2}\)See Ref. \(^{26}\) for a study of the properties of different methods to estimate the \(p\)-value in a coincident search for transient GW signals.
C. Combining analyses

After running on the data collected by the detectors, each search algorithm produces a trigger list with times and associated \( p \)-values \( \mathcal{P} \). We combine the two lists together to form a single list of triggers ranked by their \( p \)-value. To avoid double counting of events, we remove triggers within 100 ms of a more significant trigger found by the other search algorithm. To account for the use of two search algorithms, we apply a trials factor of 2 to produce the final \( p \)-value of our search,

\[
\bar{\mathcal{P}} = 1 - (1 - \mathcal{P})^2.
\]

This assumes that the triggers produced by the two algorithms are independent; a correlation in the two lists of triggers from the pipelines would reduce the effective trials factor, making 2 a conservative choice. Of the top 150 triggers output by the two pipelines, only GW150914 is common between the lists, indicating that the noise triggers are independent here. We consider \( \bar{\mathcal{P}} \) as the ranking statistic for the combined search algorithm. Excluding GW150914, LVT151012, and GW151226, the most significant trigger has \( \bar{\mathcal{P}} = 0.26 \), well below the significance needed to be considered as a detection candidate.

III. UPPER LIMITS ON RATES

Since no IMBHB coalescences were detected during O1, we can calculate upper limits on the astrophysical rate (density) of such events. With the loudest-event method [37], if the most significant IMBHB trigger is consistent with noise, the 90% confidence upper limit is given by

\[
R_{90\%} = -\ln(0.1) \frac{\langle V_T \rangle}{\langle V_T \rangle} = 2.303 \frac{\langle V_T \rangle}{\langle V_T \rangle},
\]

where \( \langle V_T \rangle \) is the averaged spacetime volume to which our search is sensitive at the loudest-event threshold. We compute \( \langle V_T \rangle \) by injecting a large number of simulated waveforms into the O1 data, then analyzing the data with both pipelines (GstLAL and cWB) to produce a list of combined \( p \)-values \( \bar{\mathcal{P}} \). A simulated signal is considered to be detected by the search if \( \bar{\mathcal{P}} \) is smaller than the \( p \)-value of the loudest event, 0.26. The sensitive \( \langle V_T \rangle \) is then given by

\[
\langle V_T \rangle = T_0 \int dz d\theta \frac{dV_c}{dz} \frac{1}{1+z} s(\theta) f(z, \theta),
\]

where \( T_0 \) is the total time covered by the injections (in the detector frame), \( V_c(z) \) is the comoving volume contained within a sphere out to redshift \( z \) [38], \( s(\theta) \) is the injection distribution of binary parameters \( \theta \) (e.g., masses, spins, orientation angles, distance), and \( 0 \leq f(z, \theta) \leq 1 \) is the selection function indicating the fraction of injections with redshift \( z \) and parameters \( \theta \) that are detected by our search. We evaluate the integral (3) using a Monte Carlo technique.

The injected waveforms are generated using a spin-aligned effective-one-body model [24], which is the waveform model used as a base for the reduced-order model [25] that the GstLAL search pipeline used for its template bank. Precession and higher-order modes are possibly important for IMBHB detection [39–45], particularly for sources with

---

3Since the noise sources are uncorrelated between H1 and L1, introducing relative time delays larger than the GW travel time (\( \lesssim 10 \) ms) is an effective way to generate an empirical noise distribution.
more extreme mass ratios; however, we neglect both effects due to current limitations in the waveform models.

Since the true population of IMBHBs, and thus the true function $s(\theta)$, is unknown, we focus on placing limits on 12 specific locations in the IMBHB parameter space. We choose 10 specific combinations of masses (see Table I). For 9 of these mass combinations, we consider only nonspinning black holes. In the case $m_1 = m_2 = 100 M_\odot$, we consider nonspinning black holes and two spinning cases. In both spinning cases, we choose dimensionless spins $\chi_{1,2}$ of magnitude 0.8 which are aligned with each other. In one case, the spins are also aligned with the orbital angular momentum of the system ($\chi_1 = \chi_2 = 0.8$); in the other, they are antialigned ($\chi_1 = \chi_2 = -0.8$). Angular parameters (i.e., binary orientation and sky location) are chosen from a uniform distribution on a sphere.

The luminosity distances of the sources are chosen approximately uniformly in comoving volume out to a maximum redshift $z = 1.4$. The sources are distributed uniformly in the O1 observation time ($T_0 \approx 130$ days), with a correction factor to account for time dilation. In the detector frame, the injections are spaced by 100 s on average. The total number of injections in each set is $N_{\text{total}} \approx 112000$, with some slight variation between sets due to the random nature of assigning injection times. Each set includes times during which the detectors were not taking coincident data; the procedure is insensitive to their inclusion in the total. The total spacetime volume covered by the injection sets is $\langle VT \rangle_{\text{total}} \approx 35$ Gpc$^3$ yr$^{-1}$. With these choices, expression (3) for the sensitive $\langle VT \rangle$ reduces to the form

$$\langle VT \rangle = \frac{N_{\text{below cutoff}}}{N_{\text{total}}} \langle VT \rangle_{\text{total}},$$

where $N_{\text{below cutoff}}$ is the number of injections assigned a $p$-value lower than 0.26.

The results are given in Table I. The table shows the 90% confidence rate upper limit for each of the 12 injection sets. Amplitude and phase errors arising from detector calibration [46] have not been included in the analysis; we expect uncertainty in $R_{90\%}$ to be $\approx 18\%$ because of the $\approx 6\%$ uncertainty in the detectors’ amplitude calibration [5]. The tightest bound is placed on the merger of two 100 $M_\odot$ black holes whose spins are aligned with their orbital angular momentum: the rate of these mergers is constrained to be less than 0.93 Gpc$^{-3}$ yr$^{-1}$. Since IMBHB merger rates are commonly expressed in events per GC per Gyr, we convert our results into these units by assuming, for the sake of simplicity, a redshift-independent cosmic density of 3 GCMpc$^{-3}$ [47], yielding a minimal $R_{90\%} \approx 0.3$ GCl$^{-1}$ Gyr$^{-1}$.

We also report a sensitive distance,

$$D_{\langle VT \rangle} = \left(\frac{3 \langle VT \rangle}{4 \pi T_0 a}\right)^{1/3},$$

where $T_0 < T_0$ is the total time analyzed by the search. The sensitive distance is analogous to the sense-monitor range [48], except that (5) includes cosmological effects. It is given in Table I for the combined $\langle VT \rangle$, used to generate $R_{90\%}$, as well as for the GstLAL and cWB search algorithms individually. The searches are most sensitive to binaries with $m_1 = m_2 = 100 M_\odot$ and aligned spins. Figure 2 also reports $R_{90\%}$ and $D_{\langle VT \rangle}$ for the combined search with lines of constant mass ratio $q = m_2/m_1$ and total mass $M = m_1 + m_2$ to guide the eye.

IV. ASTROPHYSICAL IMPLICATIONS

There are currently few good candidates for IMBHBs, but if one extrapolates the observed relation between supermassive black holes and the masses of their host galaxies to lower-mass systems, it is plausible to infer the existence of IMBHBs [49–56]. While the formation channel of IMBHs is unknown, there are a small number of proposed scenarios: (i) the direct collapse of massive first-generation, low-metallicity Population III stars [57–60], (ii) runaway mergers of massive main sequence stars in dense stellar clusters [61–65], (iii) the accretion of residual gas onto stellar-mass black holes [66], and (iv) chemically homogeneous evolution [67].

It has been suggested that the most likely locations to find IMBHs are at the centers of GCs [68–80]. It follows that these are also the most likely places to find IMBHBs. Again, while the formation mechanisms are unknown, it is postulated that an IMBHB can be formed in a GC with a fraction of binary stars higher than $\approx 10\%$ [81] or as a result of a merger of two clusters, each of which contains an IMBH [82,83]. While no direct observational evidence of IMBHs exists, this hypothesis is supported by recent simulations of dense stellar systems [84]. Measurements of an IMBH’s components would allow us to not only constrain IMBH formation channels, but also make statements on the link between IMBHs and both ultraluminous [85] and hyperluminous [86–88] x-ray systems.

This density encompasses GCs with a range of masses and central concentrations; we make the further simplifying assumption that all GCs have the potential to form IMBHs with the masses we consider.

Since IMBHs are potentially formed via different channels than stellar-mass black holes, we do not attempt to extrapolate the BBH mass distribution to IMBHBs. The O1 BBH merger rate and mass distribution reported in [5,10] were calculated assuming that the total mass is less than 100 $M_\odot$.  

\[4\] A flat cosmology with an incorrect value of $\Omega_m = 0.3156$ (instead of 0.3065) was used to generate the injection sets. We find that the error has no significant effect on our results, introducing an error of less than 1%. 

\[5\] Since IMBHs are potentially formed via different channels than stellar-mass black holes, we do not attempt to extrapolate the BBH mass distribution to IMBHBs. The O1 BBH merger rate and mass distribution reported in [5,10] were calculated assuming that the total mass is less than 100 $M_\odot$. 

022001-5
As stated in Table I, the minimal $R_{90\%}$ is found to be $\approx 0.3 \text{ GC}^{-1} \text{Gyr}^{-1}$. The improvement in detector sensitivity since the S6 run means that this result is nearly 2 orders of magnitude lower than the lowest upper limit set using previous LIGO-Virgo data [13,16]. This number is within a factor of a few of 0.1 GC$^{-1}$ Gyr$^{-1}$, the IMBHB merger rate corresponding to one event occurring in each GC within the lifetime of the cluster (assumed equal to 10 Gyr), although it only refers to a single point in the IMBH mass-spin parameter space and not to the full physical distribution of IMBHs. The bounds are compatible with rate predictions coming from astrophysical models of IMBH formation [83,89,90]. To make a full comparison of the upper limits with predictions, or with the BBH merger rate (9–240 Gpc$^{-3}$ yr$^{-1}$ [5,10]), it would be necessary to assume a mass, spin, and redshift distribution for IMBH mergers; this distribution is currently uncertain, so we defer a comparison to future studies.

Further improvements to the detector sensitivity in the next observing runs will allow us to increasingly improve the IMBHB merger-rate estimation and provide relevant constraints on the merger rate in the local Universe. A single GW detection of an IMBHB merger could provide the first conclusive proof of the existence of IMBHs in the Universe [91–93]. Multiple detections, where astrophysically important parameters, such as mass and spin, are measured, would allow us to make statements not only on the formation and evolutionary channels of IMBHs but also on their link with other observed phenomena.

V. CONCLUSION

This paper describes a search for intermediate mass black hole binaries during the first observing run of the Advanced LIGO detectors. Due to improvement in detector sensitivity, this run had an increase in search horizon of a factor of $\approx 6$ compared to the previous science run. The search uses the combined information from a modeled matched-filter pipeline and an unmodeled transient burst pipeline. While no IMBHBs were found, 90% confidence limits were placed on the merger rates of IMBHs in the local Universe. The minimum merger rate of $\approx 0.3 \text{ GC}^{-1} \text{Gyr}^{-1}$ constitutes an improvement of almost 2 orders of magnitude over the previous search results. The results presented here are based on non-precessing and, in most cases, nonspinning waveforms, that also omit higher modes. It is believed that these higher-order physical effects may be important for IMBHBs, but they should be less important for the near equal-mass systems where we can set best upper limits. We plan to include these effects in future analyses. It is also believed that continued improvements in the detector performance during future observing runs [94] will allow us to further tighten these bounds and may lead to the first detections of IMBHs.
