Review

Novel Insights into Membrane Targeting of B Cell Lymphoma

Charlotte M. de Winde,¹ Suraya Elfrink,¹ and Annemiek B. van Spriel¹,*

Standard therapy of patients with B cell non-Hodgkin lymphoma (B-NHL) predominantly consists of chemotherapy combined with anti-CD20 (e.g., rituximab) immunotherapy. However, relapse of aggressive B-NHL occurs frequently, and this may coincide with therapy resistance. This demonstrates the urgent need for exploring new lymphoma-targeted therapies. We review here recent insights in the pathophysiology of B-NHL and discuss CD20 and three alternative membrane targets (B cell receptor, immune checkpoints PD-1/PD-L1, tetraspanin CD37) that are currently in the spotlight for B-NHL treatment. Furthermore, we present a novel concept in which the plasma membrane organization of the lymphoma B cell determines the efficacy of membrane-targeted therapies, and this has consequences for treatment application and clinical outcome in patients with B cell lymphoma.

Origin of B Cell Non-Hodgkin Lymphoma

B cells undergo several distinct phases of development, starting from pre-B cells in the bone marrow towards ultimately their differentiation into antibody-producing plasma cells and memory B cells. Upon encountering specific antigens, germinal centers (GCs, see Glossary) are formed within the lymph node, where B cells undergo somatic hypermutation (SHM) and class-switch recombination (CSR) to generate a high-affinity B cell receptor (BCR). However, SHM and CSR are error-prone mechanisms, and hence the majority of B cell non-Hodgkin lymphomas (B-NHL) arise from GC B cells [1]. These GC-derived B cell lymphomas frequently harbor chromosomal translocations of proto-oncogenes such as BCL2, BCL6, or MYC that are relocated under the control of the active immunoglobulin heavy chain (IgH) locus [1,2]. Because these translocations often involve the non-productively rearranged Ig loci, most lymphomas still express a functional BCR [1].

The GC-derived B-NHLs include follicular lymphoma (FL), Burkitt lymphoma (BL), and diffuse large B cell lymphoma (DLBCL). DLBCL is the most prevalent type, accounting for approximately one third of all NHL cases. Two subtypes of DLBCL have been identified: germinal center B cell-like (GCB-) DLBCL, arising from GC B cells, and activated B cell-like (ABC-) DLBCL, which has a post-GC origin [3]. ABC-DLBCL is characterized by constitutively active BCR/NF-κB signaling [4], and has a worse prognosis than GCB-DLBCL [3]. The hallmark of BL is translocation of MYC to the IgH locus [5]. Both DLBCL and BL are aggressive cancers, in contrast to FL which is an indolent lymphoma. However, in a large proportion of FL cases the disease transforms into the more aggressive DLBCL [6]. Current first-line treatment of DLBCL consists of the combination of rituximab (anti-CD20 monoclonal antibody, mAb) with CHOP-based chemotherapy, frequently followed by subsequent radiotherapy. BL is treated with CHOP-based chemotherapy, sometimes combined with rituximab. For FL, a watch-and-wait policy is frequently applied. In case of treatment indication, first-line treatment consists of

rituximab combined with CHOP- or CVP-based chemotherapy, with or without subsequent radiotherapy. The exact protocol depends on the diagnosis and condition of the patient [7–9].

Although immunotherapy with rituximab has significantly improved the clinical outcome of patients with B cell malignancies [10,11], many patients with DLBCL [12], BL [11], or FL [13] suffer from treatment failure or relapse. Several novel targeted therapies are currently under (pre)clinical investigation, including therapies targeting the tumor microenvironment [reviewed in [14]] and therapies targeting the lymphoma cells directly, either intracellular or at the membrane [reviewed in [15]]. Targeting membrane proteins to treat cancer has been extensively studied by researchers and clinicians during the past two decades because the cell surface is the most accessible part of the cell. Rituximab is a clear example of successful antibody-based immunotherapy targeting a membrane protein. Antibody-based membrane-targeted therapies act through different mechanisms, including direct cell death signaling, antibody-dependent cell-mediated cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). In this review we focus on recent developments and new membrane-targeted therapies for GC-derived B cell lymphoma (Figure 1A). Furthermore, we propose a model illustrating the dynamic cell-surface protein landscape of lymphoma B cells that influences the efficacy of membrane-targeted therapies in B-NHL.

CD20 as the First B Cell-Specific Membrane Target to Treat B-NHL

Anti-CD20 mAb rituximab represents the first mAb approved for cancer therapy by the FDA in 1997. CD20 is a four-transmembrane protein expressed on mature B cells and is involved in B cell activation and differentiation, mainly by controlling calcium influx [16]. CD20 was selected in the early 1980s as new target for B-NHL because the majority of B-NHL cells (90%) express a high density of CD20 at the cell surface [17]. Pro-B cells and antibody-producing plasma cells do not express CD20, and are therefore not vulnerable to CD20 targeting. As such, the healthy B cell pool is restored after rituximab treatment and B cell immune responses are largely preserved.

Anti-CD20 mAbs have been classified into types I and II [18], both of which induce ADCC. Type I mAbs (e.g., rituximab and ofatumumab) are regarded as the most potent antibodies because of their capacity to initiate CDC, in contrast to type II mAbs (e.g., obinutuzumab). Furthermore, type II mAbs may induce direct cell death (Figure 1B), although the exact mechanism remains to be elucidated. Upon type I mAb binding, CD20 is redistributed to specific microdomains, including lipid rafts and tetraspanin-enriched microdomains (Box 1), which stimulates clustering of the antibody Fc regions involved in CDC. Unfortunately, Fc receptor polymorphisms and downregulation of CD20 caused by repeated exposure to rituximab [19] demonstrate the urgent need for development of alternative membrane-targeted strategies.

**Glossary**

**Antibody-dependent cell-mediated cytotoxicity (ADCC):** the induction of cell death via binding of an antibody to its cell surface target. The Fc tail of the antibody engages Fc receptor-expressing immune cells, such as natural killer (NK) cells and macrophages, that kill the antibody-bound target (i.e., tumor cell).

**CHOP:** abbreviation for cyclophosphamide–doxorubicin (hydroxydaunorubicin)–vincristine (oncovin)–prednisone, a chemotherapeutic cocktail mostly used to treat B cell non-Hodgkin lymphoma patients. CHOP is often used in combination with anti-CD20 mAb rituximab (R-CHOP).

**Class-switch recombination (CSR):** the process by which the isotype or class of immunoglobulin produced by the B cell is switched, for example from IgM to IgG. This takes place via genomic changes in the locus encoding the constant region of the Ig heavy chain.

**Complement-dependent cytotoxicity (CDC):** the induction of cell death via activation of the complement system (C1q binding to the antibody), which leads to lysis of the target (i.e., tumor) cell membrane.

**CVP:** abbreviation for cyclophosphamide–vincristine–prednisone, a chemotherapeutic cocktail used to treat follicular lymphoma patients.

**Diffuse large B cell lymphoma (DLBCL):** the most common and aggressive type of B cell non-Hodgkin lymphoma, accounting for approximately one third of all non-Hodgkin lymphoma cases.

**Follicular lymphoma (FL):** the second most common B cell non-Hodgkin lymphoma. FL is an indolent cancer, but can transform into the more aggressive DLBCL.

**Germinal center:** an area in B cell follicles of secondary lymphoid tissues where B cell proliferation, class-switch recombination, somatic hypermutation, and selection take place.

**Somatic hypermutation (SHM):** the process in which the Ig-encoding DNA of mature B cells is subjected...
to the introduction of random point mutations. These modifications occur in the variable region of the Ig gene leading to affinity maturation (increased-affinity BCR).

(See figure legend on the bottom of the next page.)
Emerging Membrane-Targeted Therapies for B Cell Lymphoma

In addition to CD20, numerous other potential membrane targets have been investigated in lymphoma, including CD19, CD22, CD23, CD37, CD47, CD52, CD74, CD79α, CD80, HLA-DR, and the BCR (idiotype). Furthermore, immune checkpoint inhibitors that target programmed cell death protein 1 (PD-1) and programmed cell death ligand 1 (PD-L1) are currently in the spotlight for treatment of B-NHL. Targeting of some of these cell-surface proteins with mAbs has shown promising therapeutic efficacy, but targeting others seems less suitable because of limited specificity (e.g., CD80 and HLA-DR are very broadly expressed) or resistance development (e.g., by antigen shedding or internalization). A few new mAbs directed against B cell surface proteins currently tested in clinical trials show promising results either as first-line therapy in combination with rituximab or as monotherapy for heavily pretreated B-NHL patients (e.g., anti-CD22, epratuzumab; anti-CD37, otlertuzumab; anti-CD74, milatuzumab) (reviewed in [15]). Future antibody engineering studies, including conjugation to radio/immunotoxins or the generation of bispecific antibodies, may further improve their anti-lymphoma potency. Below we will discuss recent results and focus on novel developments in targeting membrane proteins in B-NHL, including immune checkpoints and tetraspanins (Figure 1).

Aberrant BCR Function in B-NHL

The BCR, a membrane-bound Ig, can be divided into five classes (IgG, IgD, IgM, IgA, or IgE) that are important for antigen recognition and initiation of signaling events leading to B cell survival, proliferation, and migration [20]. The BCR forms a complex with CD79α (or Igα) and CD79β (or Igβ) which both contain an immunoreceptor tyrosine-based activation motif (ITAM) to transmit intracellular signaling. Upon antigen binding, the conformational state of the BCR changes to initiate downstream signaling, but the underlying molecular mechanisms are still debated. The ‘conformation-induced oligomerization model’, which proposes that single BCRs oligomerize upon antigen recognition [21], has recently been challenged by super-resolution studies. This has led to convincing evidence for the ‘dissociation–activation model’ in which BCR oligomers dissociate upon antigen binding, gaining an open conformation [22,23]. This conformational change influences the distribution of BCR coreceptors CD19 and CD20 that interact with IgD oligomers on resting B cells, and relocate to IgM oligomers upon B cell activation [23]. These changes in plasma membrane organization are controlled by a superfamily of membrane-organizing proteins, the tetraspanins (Box 2). Tetraspanin CD81 is required for reorganization of CD19 to BCR nanoclusters, and this enables binding of signaling proteins to the intracellular domain of CD19 and initiation of signaling downstream of the BCR [24,25].

Two modes of BCR signaling have been described. (i) Active signaling upon antigen binding to the BCR, leading to NF-κB activation via Syk, phosphoinositide 3-kinase (PI3K), and Bruton’s tyrosine kinase (BTK); and (ii) tonic signaling, an antigen-independent mechanism required for B
cell survival which occurs in mature resting B cells via activation of PI3K and protein kinase B (AKT) (reviewed in [26]) (Figure 1C). In most GC-derived B cell lymphomas, BCR signaling is disturbed, resulting in enhanced B cell survival and proliferation. BL shows tonic BCR signaling (Figure 1C) via constitutive activation of the PI3K pathway driven by MYC translocation to the IgH locus during SHM [5,27]. Chronic active BCR signaling is seen in ABC-DLBCL, as evidenced by knockdown of BTK or components of the BCR complex that induces killing of lymphoma cells [4]. By contrast, GCB-DLBCL cells were not killed, indicating they do not require BCR signaling to survive. In the majority of ABC-DLBCL cases, self-antigens present in the tumor microenvironment may drive continuous BCR stimulation (Figure 1C) [28]. The presence of BCR clusters on ABC-DLBCL cells resembles BCR clusters observed on normal B cells following antigen stimulation [4]. In 10% of ABC-DLBCL cases, gain-of-function mutations in CARMA1 (also known as CARD11) were found to result in continuous NF-κB activation [29]. Furthermore, in 20% of ABC-DLBCL cases, somatic mutations in the CD79α/CD79β ITAM domains induced chronic active BCR signaling via inhibition of BCR endocytosis and prevention of binding of Lyn to CD79β [4].

In FL, constitutive BCR signaling induced by presence of (self-)antigens has been found in only 20–25% of the cases [30,31], whereas the majority of FL cases (80%) bear somatic mutations in the IgM-BCR leading to increased incorporation of N-glycosylation sites [32,33]. If this occurs in the antigen-binding side of the BCR it may prevent binding of (self-)antigens, but in turn can be recognized and stimulated by lectin receptors on myeloid cells in the tumor microenvironment [34,35]. This results in reorganization of the BCR complex (including CD19) into signaling platforms and persistent antigen-independent signaling via Syk and BTK.

Currently, different small-molecule inhibitors targeting signaling proteins downstream of the BCR (Syk, Lyn, PI3K, BTK) are under investigation as a novel therapy for B-NHL (reviewed in [26]). Nevertheless, increased understanding of the conformational changes taking place in the BCR upon antigen binding may open new opportunities to directly target the BCR itself. This idea was originally explored in the 1980s when treatment of lymphoma patients with anti-idiotype antibodies (targeting the variable region of the BCR) revealed promising clinical results [36]. However, this approach required the generation of patient-specific idiotype antibodies, hampering clinical implementation. Recently, a new tool has been developed to screen and target tumor-specific idiotypes with small peptides linked to a pre-made IgG-Fc protein, so-called anti-idiotype ‘peptibodies’ [37], which directly induce cell death via BCR signaling and ADCC. Furthermore, the anti-CD79β antibody–drug conjugate polatuzumab vedotin may be promising for the treatment of B-NHL patients [38], and is currently being investigated in clinical trials (https://clinicaltrials.gov).
Therapeutic strategies targeting the BCR coreceptor CD19 are encouraging for patients with relapsed/refractory B-NHL. CD19 chimeric-antigen receptors expressed by T cells (CD19-CAR T cells) consist of an extracellular domain specific for CD19 on B-NHL cells and intracellular domains to provide T cell stimulatory signals (e.g., CD3ζ and CD28). Adoptive transfer of CD19-CAR T cells has given complete responses in ~50–60% of B-NHL patients in Phase I/II clinical trials [39]. Furthermore, blinatumomab, a CD19/CD3 bispecific T cell engager (BiTE) generated from the antigen-binding regions of the single-chain antibodies of CD19 and CD3, is approved by the FDA for treatment of acute lymphoblastic leukemia (ALL), and clinical results are currently being evaluated for the treatment of other B cell malignancies including B-NHL [40]. Future research will be necessary to determine the consequences of targeting the BCR complex in B-NHL patients, and in particular how this changes BCR conformation and downstream signaling.

**Function and Targeting of Immune Checkpoints PD-1/PD-L1 in B-NHL**

Cancer immunotherapy was chosen as the scientific breakthrough of 2013 by Science journal [41] in view of promising results with immune checkpoint inhibitors. Immune checkpoints are proteins that regulate immune cell activation to maintain self-tolerance and prevent autoimmunity (reviewed in [42]). More specifically, these checkpoints play an important role in controlling T cell priming and activation. For example, PD-1 on T cells transfers an inhibitory signal when engaged by PD-L1 expressed by tumor cells or activated T cells.

Tumor cells may exploit these checkpoints to escape or suppress the immune system by (over) expressing PD-L1. Currently, anti-PD-1 mAbs (pembrolizumab and nivolumab) and anti-PD-L1 mAbs (atezolizumab and durvalumab) demonstrate promising clinical results in the treatment of different solid tumors, including metastatic melanoma, urothelial carcinoma, and advanced non-small cell lung carcinoma (reviewed in [43]). This treatment strategy has also gained more attention in the B cell lymphoma field (Figure 1D) (reviewed in [42]), and nivolumab has recently been approved by the FDA for the treatment of relapsed/refractory Hodgkin lymphoma in view of promising clinical results [44].

For DLBCL, promising clinical results have been obtained with the anti-PD-1 mAbs pidilizumab and nivolumab [45,46], and both anti-PD-1 and anti-PD-L1 mAbs are currently being tested in clinical trials (https://clinicaltrials.gov/). It has been shown that a subset of ABC-DLBCL tumors (11–31%) displays high expression of PD-L1, in contrast to GCB-DLBCL tumors that virtually lack expression of PD-L1. This high PD-L1 expression has been suggested to underlie the poorer prognosis of ABC-DLBCL patients compared to patients with GCB-DLBCL [47,48]. Because PD-L1 expression is restricted to a minority of DLBCL patients, it is likely that only this group will benefit from immune checkpoint blockade [48,49].

Although PD-L1 is rarely expressed in FL cells [42,47], FL patients may still benefit from immune checkpoint blockade because inhibition of PD-1-expressing tumor-infiltrating T cells by PD-L1-expressing non-tumor cells in the tumor microenvironment can be reversed [50]. This has been supported by clinical studies demonstrating good responses in FL patients treated with anti-PD-1 mAbs (nivolumab and pidilizumab) [46,51]. Trials with pembrolizumab in FL patients are currently ongoing (https://clinicaltrials.gov/). Several studies have reported that BL cells do not express PD-L1 [47,49], and PD-1/PD-L1 checkpoint inhibitors have therefore not yet been studied in BL. Nonetheless, the promising results of immune checkpoint inhibition in FL, which rarely expresses PD-L1, may be translated to BL. Taken together, targeting the immune checkpoint membrane proteins PD-1/PD-L1 seems to be a promising novel treatment option for a selected group of ABC-DLBCL and FL patients. However, it is still debated whether expression of PD-1/PD-L1 is of prognostic value for immune checkpoint inhibition therapy in B-NHL [52,53].
CD37 Rediscovered as a B Cell Membrane Target in the Treatment of B-NHL

Tetraspanin CD37 recently regained attention as promising membrane target for mature B cell malignancies (Box 2). CD37 expression is restricted to the immune system, with highest abundance on mature B cells, and is absent in earlier stages of B cell development and decreased on plasma cells [54,55]. This pattern is also reflected in different B cell lymphomas: CD37 is mostly expressed on B cell malignancies derived from mature B cells (although ~50% of DLBCL patients lack CD37 [56,57], as discussed below), but not in acute lymphoblastic lymphoma and multiple myeloma [58]. Comparable to CD20, this distinct expression pattern makes CD37 an interesting target in GC-derived B cell lymphomas. Already in 1989 the first CD37-targeting antibody (labeled with the radioactive isotope iodine 131) was tested in 10 refractory NHL patients, with promising clinical results [59]. However, because anti-CD20 treatment (rituximab) was introduced at the same time, anti-CD37 therapy was forgotten for almost two decades until the development of a novel CD37-targeting mAb-derived polypeptide re-established interest in this target [60].

Several different antibody-based CD37-targeting approaches are currently under investigation in Phase I and II trials for chronic lymphocytic leukemia (CLL) and refractory or relapsed NHL patients (https://clinicaltrials.gov; reviewed in [61]) (Figure 1E). Otltuzumab (TRU-016), a humanized, antibody-derived CD37-targeting peptide, is closest to general clinical application in B cell malignancies. In a randomized Phase II study, relapsed CLL patients treated with the chemotherapeutic bendamustine plus otltuzumab showed increased progression-free survival compared to patients treated with bendamustine alone [62].

The antitumor mechanisms by which anti-CD37 agents act include ADCC, CDC, and direct apoptosis signaling [60,63,64]. In addition, CD37–antibody complexes are known to be internalized, and this has led to the generation of novel anti-CD37 agents coupled to toxins (IMGN529, an anti-CD37 antibody conjugated to an anti-microtubule agent) [64] or radioactive labels (177Lu-tetulomab) [65]. Both agents showed promising results in NHL xenograft mouse models [64,65]. Moreover, 177Lu-tetulomab was internalized with a higher efficiency than 177Lu-rituximab complexes in vitro [65], and IMGN529 showed increased activity compared to rituximab or CVP chemotherapy in a FL-derived xenograft mouse model [64]. A Phase I clinical trial completed in July 2016 studied IMGN529 in relapsed/refractory NHL and CLL patients (NCT01534715), and several Phase I/II clinical studies to test 177Lu-tetulomab (Beta-lutin) are currently including NHL patients (https://clinicaltrials.gov).

Furthermore, new insights into the function of CD37 have prompted interest in combination strategies. CD37 is important for the survival of IgG1-secreting plasma cells through the membrane organization of α4β1 integrins and subsequent activation of the AKT signaling pathway [66]. The intracellular tails of CD37 can be tyrosine phosphorylated, leading to the initiation of apoptotic signaling via the N-terminal immunoreceptor tyrosine-based inhibition motif (ITIM)-like domain, and opposing survival signaling via its C-terminal ITAM domain [63]. Both pathways are induced by the CD37-targeting mAb-derived polypeptide SMIP-016 which was the basis for the development of TRU-016. Although signaling to apoptosis is the most prominent, the efficiency of CD37 targeting could be improved using combination therapy with pro-survival PI3K inhibitors [63].

Importantly, recent studies revealed that ~50% of DLBCL tumors are negative for CD37 expression, and its loss is a potential risk factor for R-CHOP resistance and poor survival rates independent of the International Prognostic Index (IPI) [56,57]. The underlying mechanism involves enhanced activation of the IL-6 signaling pathway in CD37-negative lymphomas [56]. IL-6 is known to be involved in the development of many cancers, including hematological
Figure 2. Plasma Membrane Organization of Lymphoma B cells Determines the Efficacy of Membrane-Targeted Therapies. The cell membrane (light area) is highly organized into specialized microdomains (dark area) that are formed by dynamic homotypic (e.g., CD20–CD20) and heterotypic (e.g., CD19–CD81) protein–protein interactions. Upon ligand–receptor binding (e.g., IL-6 to IL-6R), induction of a conformational change can lead to rearrangement of protein–protein interactions and reorganization of the membrane landscape. Lymphoma B cells have a disrupted membrane protein organization, for example as a result of constant activation of the B cell receptor (BCR) by (self-)antigens, overexpression of PD-L1, or loss of tetraspanin CD37. In addition, BCR activation results in CD20 dissociation and redistribution, and anti-CD20 targeted therapy using rituximab induces CD20 clustering. These data support a model in which the microdomain organization of lymphoma cells determines the efficacy of membrane-targeted therapies, which has important implications for treatment application and clinical outcome.
malignancies, and several IL-6-targeting strategies have been developed (reviewed in [67,68]).
Based on these studies, inhibition of IL-6 signaling (using mAb anti-IL-6 siltuximab or anti-IL-6R
tocilizumab) may represent a potential new treatment strategy for patients with CD37-negative
DLBCL (Figure 1E).

Dynamic Protein Interactions Shape the Organization of the B Cell
Membrane

Proteins in the plasma membrane are not randomly distributed, and instead are localized to
specific microdomains (Box 1). One of the first models of membrane protein organization on the
B cell membrane was published two decades ago [69]. Using flow cytometry energy transfer
(FCET) it was shown that CD20 interacts with tetraspanins CD53, CD81, and CD82 on a
lymphoma B cell line. In addition, confocal microscopy [70] and coimmunoprecipitation [71]
revealed that CD20 also clusters with the BCR in specialized microdomains, indicating that they
are localized in lipid rafts or tetraspanin microdomains (Box 1). The BCR dissociates from CD20
to distinct lipid rafts upon stimulation, and is subsequently internalized [70]. A direct interaction
between CD20 and the BCR was recently confirmed using proximity-ligation assay [23]. It was
shown that CD20 (similar to CD19) interacts with different BCR classes (IgD/IgM) on resting and
antigen-activated human B cells, demonstrating redistribution of CD20 upon BCR stimulation.

CD20 has been shown to interact with several tetraspanins (CD53, CD81, and CD82) [69],
although CD37 was not studied. Recently we discovered that both protein and mRNA
expression of CD20 and CD37 on lymphoma B cells are correlated [57]. Although this is in
line with the inferior outcome of CD37-negative DLBCL patients upon R-CHOP therapy, the
prognostic significance of CD37 seems to be independent of CD20 mRNA levels [57]. Further
research is necessary to verify a possible direct interaction and co-expression patterns of CD37
and CD20 in B-NHL cases.

These studies indicate that the organization of the B cell membrane is shaped by dynamic
protein–protein interactions that are subject to change upon B cell activation. This protein
organization is not only important for B cell function but also for the efficacy of membrane-
targeted therapies, as illustrated by clustering of CD20 upon rituximab binding [18]. Likewise,
CD37-targeting using SMIP-016 resulted in translocation into microdomains, and translocation
was required for efficient tumor cell apoptosis [63]. On lymphoma B cells, changes in mem-
brane protein expression (e.g., absence of CD37) or protein clustering (e.g., conformational
changes of the BCR upon binding of self-antigens) will change the protein organization and
interactions at the plasma membrane. Based on these studies we propose that the changed
cell-surface protein landscape of lymphoma B cells has consequences for the efficacy and
application of membrane-targeted therapies (Figure 2). Moreover, targeted therapies may alter
dynamic protein–protein interactions, affecting plasma membrane organization and down-
stream signaling.

Concluding Remarks

Many patients with B-NHL still face treatment failure or relapse upon standard therapy,
emphasizing the urgent need for new treatment options. The plasma membrane is the most
easily accessible part of the tumor cell, and exposes a variety of different proteins which may
serve as treatment targets. We have discussed the widely studied target CD20 and three
alternative membrane targets (BCR, PD-L1, and CD37) that are currently under investigation in
clinical trials to treat B-NHL. Furthermore, patients with CD37-negative lymphoma B cells have
a dismal prognosis and may benefit from anti-IL-6(R)-targeted therapy.
Membrane proteins interact with each other and thereby facilitate various cell biological processes, including initiation of downstream signaling. B cell activation will affect these protein interactions through induction of new interactions, more clustering, or alternatively by preventing specific interactions. Evidence is accumulating that lymphoma B cells contain aberrant cell-surface protein expression and organization, and this has important consequences for both the application and outcome of membrane-targeted therapy for B-NHL patients.

We are only at the beginning of understanding the membrane organization of normal and malignant B cells, and further research will be necessary to address the outstanding issues in this new and exciting field (see Outstanding Questions). In particular, recent advances in super-resolution microscopy now enable imaging the membrane composition of lymphoma cells at the nanoscale level [72]. Taking into account that lymphomas are heterogeneous tumors [2], targeting membrane proteins as monotherapy will probably not be sufficient for complete tumor eradication. Thus, the use of combination therapies, such as immuno-chemotherapy and the additional use of small-molecule inhibitors, will be important in the future treatment of B cell non-Hodgkin lymphoma.
