Revealing the relation between the structure, Li-ion conductivity and solid-state battery performance of the argyrodite Li$_6$PS$_5$Br solid electrolyte

Chuang Yu,$^a$ Swapna Ganapathy,$^a$ Ernst R. H. van Eck,$^b$ Lambert van Eijck,$^a$ Shibabrata Basak,$^c$ Yanyan Liu,$^d$ Long Zhang,$^d$ Henny W. Zandbergen$^c$ and Marnix Wagemaker$^a$ $^{*ab}$

Based on its high Li-ion conductivity, argyrodite Li$_6$PS$_5$Br is a promising solid electrolyte for all-solid-state batteries. However, more understanding is required on the relation between the solid electrolyte conductivity and the solid-state battery performance with the argyrodite structure, crystallinity and particle size that depend on the synthesis conditions. In the present study, this relationship is investigated using neutron and X-ray diffraction to determine the detailed structure and impedance as well as Li solid state NMR spectroscopy to study the Li-ion kinetics. It is found that depending on the synthesis conditions the distribution of the Br dopant over the crystallographic sites in Li$_6$PS$_5$Br is inhomogeneous, and that this may be responsible for a larger mobile Li-ion fraction in the interfacial regions in the annealed argyrodite materials. Comparing the bulk and interfacial properties of the differently prepared Li$_6$PS$_5$Br materials, it is proposed that optimal solid-state battery performance requires a different particle size for the solid electrolyte only region and the solid electrolyte in the cathode mixture. In the electrolyte region, the grain boundary resistance is minimized by annealing the argyrodite Li$_6$PS$_5$Br resulting in relatively large crystallites. In the cathode mixture however, additional particle size reduction of the Li$_6$PS$_5$Br is required to provide abundant Li$_6$PS$_5$Br–Li$_2$S interfaces that reduce the resistance of this rate limiting step in Li-ion transport. Thereby the results give insight into how to improve solid-state battery performance by controlling the solid electrolyte structure.

Introduction

Inorganic solid electrolytes for all-solid-state Li-ion batteries are attracting significant attention because of the improved safety they provide in comparison with the conventional liquid electrolyte based Li-ion batteries.$^{1,2}$ Other potential advantages include improved chemical and electrochemical stability and more efficient cell packaging, allowing higher practical energy densities, using the same anode and cathode chemistries. One of the crucial parameters for solid electrolytes is their high room temperature Li-ion conductivity that for practical applications should be in the order of $10^{-4}$ S cm$^{-1}$.1,4

Intensive research efforts have led to the discovery of several new solid electrolytes with high Li-ion conductivities including sulphides (Li$_7$S–P$_2$S$_9$, Li$_6$S–SiS$_2$, and Li$_3$S–GeS$_2$)$^{5}$–$^7$ oxides (Li$_2$La$_3$Zr$_2$O$_{12}$ and Li$_{3}x$La$_{2-3x}$TiO$_3$)$^8$ and phosphates (LiPON, Li$_{1+x}$Al$_{2-x}$Ge$_2$–x(PPO)$_3$) and Li$_{1+x}$Ti$_{2-x}$Al$_x$(PO$_4$)$_3$)$^{9,10}$ Among them, the chemically stable oxides and phosphates display relatively low ionic conductivities and high grain boundary resistances.$^9$ Sulphides generally offer higher conductivities$^{11}$ and their relatively low annealing temperatures, compared to the oxides and phosphates, apparently lead to a relatively low grain boundary resistance,$^{12,13}$ which makes them promising solid electrolytes for solid-state cells. An important family of sulphide based solid electrolytes are the Li-argyrodites Li$_6$PS$_5$X (X = Cl, Br and I) providing Li-ion conductivities in the range of $10^{-2}$ to $10^{-1}$ S cm$^{-1}$ at room temperature.$^7$ The high conductivity and the low costs of starting materials make the Li-argyrodites attractive for application in all-solid-state batteries. Previous work has demonstrated that the Li$_6$PS$_5$Cl argyrodite, with high Li-ion conductivity, can be synthesized by direct ball-milling followed by annealing, resulting in a good solid state Li-S battery performance with both S and Li$_2$S cathodes.$^{14,17}$ Although for argyrodite solid electrolytes large electrochemical stability windows have been reported,$^{18,19}$

calculations indicate a much smaller window for sulphides with an upper limit just exceeding the potential of Li$_2$S, motivating the use of Li$_2$S as a cathode material in combination with sulphide electrolytes.

To improve the all-solid-state battery performance, it is essential to develop an understanding of the influence of synthesis parameters and cycling conditions on the electrochemical performance of solid electrolytes. For argyrodite solid electrolytes, the annealing temperature appears to be very important for the Li-ion conductivity and electrochemical performance, as illustrated by the role of the halogen dopant position in the lattice, recently studied by DFT. The energy barriers for short range jumps and long range jumps were investigated by MD simulations and valence calculations indicating the detailed influence of the halogen on the diffusion mechanism. However, little is known about how annealing and ball milling strategies influence the bulk mobility as well as the macroscopic Li-ion conductivity, including across grain boundaries, and how this affects the solid-state battery performance. Additionally, little is known about the impact of the electrochemical (dis)charge window on the cycle life, which is in particular relevant in the context of the predicted limited electrochemical stability window for these sulphide electrolytes.

In the present work, a detailed study of the effect of annealing on the Li-ion dynamics in the argyrodite Li$_6$PS$_5$Br solid electrolyte has been performed. By employing both impedance spectroscopy and spin–lattice relaxation (SLR) NMR measurements, differences in the local Li-ion mobility and bulk diffusion as well as the impact of grain boundaries are revealed between differently prepared Li$_6$PS$_5$Br solid electrolyte materials. Combined Rietveld refinement of neutron and X-ray powder diffraction data were performed to probe structural differences between the prepared Li$_6$PS$_5$Br materials. Transmission electron microscopy (TEM) measurements were performed to investigate the crystallinity and the distribution of the Br dopant. Finally, cyclic voltammetry (CV) was performed to determine the optimum (dis)charge voltage window for the nano-Li$_2$S/Li$_6$PS$_5$Br/In solid-state cells. By employing the optimized electrochemical window for (dis)charging, a significant difference in the performance is observed for the differently prepared solid electrolytes, where only the solid-state cell using annealed nano-sized Li$_6$PS$_5$Br as the solid electrolyte maintained capacities above 500 mA h g$^{-1}$ (per gram of active material) for 25 cycles.

**Experimental**

Reagent-grade Li$_2$S (99.98%, Sigma-Aldrich), P$_2$S$_5$ (99%, Sigma-Aldrich), and LiBr (99.0%, Sigma-Aldrich) crystalline powders were used as starting materials. The required amount of the starting materials was ball milled together in a tungsten carbide (WC) coated (inner) stainless steel jar with 10 WC balls (8 g per ball) in an argon filled glovebox (H$_2$O, O$_2$ < 0.3 ppm) because of the reactivity of the sample with oxygen and moisture. The total weight of the mixture was almost 2.0 grams, and the ball milling speed was fixed at 500 rpm. The milling duration was varied to find the optimal milling time. After subsequent milling times, a small amount of powder was collected to perform powder XRD measurements. After the ball milling process, half of the sample was set aside as the ball-milled only Li$_6$PS$_5$Br (Li$_6$PS$_5$Br), and the remaining material was sealed in a quartz tube and annealed at 300 °C for 5 hours to obtain the annealed Li$_6$PS$_5$Br (AN-Li$_6$PS$_5$Br) solid electrolyte. The AN-Li$_6$PS$_5$Br was further milled with a rotation speed of 450 rpm for 4 h to obtain the AN-BM-Li$_6$PS$_5$Br sample.

Powder XRD patterns were collected over a 2θ range of 10–80° to identify the crystalline phases of the different samples using CuK$_{α1}$ X-rays (1.5406 Å at 45 kV and 40 mA) on an X’ Pert Pro X-ray diffractometer (PANalytical). To prevent the reaction with moisture and oxygen, the powders were sealed in an airtight XRD sample holder in an argon filled glove box. Neutron diffraction data were collected on a new neutron powder diffractometer PEARL of the TU Delft. Data were collected at room temperature using the (533) reflection of the germanium monochromator ($λ = 1.665$ Å). The sample was loaded under argon in a 6 mm diameter air-tight vanadium sample can. The sample was measured for 18 hours from 10.4–160 degrees 2θ. The sample can is under vacuum during the data collection. The data treatment consisted of a relative correction for the detection efficiency of (each of) the 1408 detector pixels and a subtraction of the background, caused by the instrument and the sample can. The X-ray and neutron diffraction data were refined simultaneously using the Rietveld method implemented in GSAS. Besides the atomic and lattice parameters, the absorption and line-broadening parameters, the crystal phase fractions, and the background were fitted. The S and Br occupancies on both the 4a and 4c crystallographic sites were restricted by setting the sum to 1 on each site.

For the TEM investigation, a suspension of each Li$_6$PS$_5$Br sample in hexane was prepared which was dropcast onto a standard gold grid with a holey carbon film, inside an argon-filled glove box. To prevent any contact with air TEM grids with the sample were loaded into a custom-made vacuum transfer TEM holder. TEM measurements were carried out on a FEI Tecnai operating at 200 kV. The morphology of the materials and the corresponding distribution of S, P, and Br were investigated by SEM and EDS.

The ionic conductivities of the Li$_6$PS$_5$Br electrolyte materials were determined by AC impedance. Stainless-steel disks were attached on both faces of the 10 mm diameter powder pellets. AC impedance measurements were performed using an Autolab (PGSTAT302N) in the frequency range of 0.1 Hz to 1 MHz with an applied voltage of 0.05 V.

Solid-state NMR measurements were performed on a Chemagnetics 400 Infinity spectrometer ($B_0 = 9.47$ T), operating at the 155.506 MHz $^7$Li resonance frequency. The π/2 pulse length was determined to be 3.1 μs with an RF field strength of 85 kHz. Chemical shifts were referenced with respect to a 0.1 M LiCl solution. The air sensitive Li$_6$PS$_5$Br materials were sealed in custom-made Teflon tubes in an argon filled glove box (H$_2$O, O$_2$ < 0.3 ppm). Variable temperature measurements were performed using a 5 mm static goniometer probe. For all three Li$_6$PS$_5$Br samples spectra were acquired in the temperature range of −100 °C to +180 °C. $T_1$ relaxation times were
determined at various temperatures using a saturation recovery experiment. Corresponding $T_1$ measurements were performed using the spin-lock method at a lock frequency of 20 kHz. Additional single pulse experiments were performed at different temperatures to determine the evolution of the line-width as a function of temperature employing a spectral width of 250 kHz. In each case a recycle delay of 3$T_1$ was used.

Laboratory-scale solid-state Li$_2$S/Li$_6$PS$_5$Br/In batteries were prepared. Commercial Li$_2$S was first milled with a rotation speed of 500 rpm for 4 h, and then milled with Li$_6$PS$_5$Br, AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br separately and super P (TIMCAL) with a weight ratio of 4 : 4 : 2 using a rotation speed of 450 rpm for 2 h to obtain the final cathode mixture. A two-layer pellet, 10 mm in diameter, consisting of 12 mg of the described cathode mixture and 88 mg Li$_6$PS$_5$Br, AN-Li$_6$PS$_5$Br, or AN-BM-Li$_6$PS$_5$Br solid electrolyte, was obtained by pressing the electrode and electrolyte powders by applying 6 tons of pressure. A piece of In foil was subsequently attached to the other side. Finally, the full solid-state battery pellet was pressed with 2 tons of pressure for 30 s. Cyclic voltammetry (CV) measurements of the solid-state battery with the AN-Li$_6$PS$_5$Br solid electrolyte were performed at different voltage windows applying a sweep rate of 0.5 mV s$^{-1}$ to determine the optimum (dis)charge voltage window. The assembled cells, either with Li$_6$PS$_5$Br, AN-Li$_6$PS$_5$Br or AN-BM-Li$_6$PS$_5$Br, were charged and discharged applying a current density of 0.064 mA cm$^{-2}$ between 0 and 3.5 V vs. In order to evaluate the electrochemical performance. The obtained capacity was normalized by the weight of Li$_2$S in the cathode.

**Results and discussion**

**Impedance, diffraction and TEM characterization of Li$_6$PS$_5$Br**

The XRD patterns of the Li$_6$PS$_5$Br samples synthesized by mechanical milling at 500 rpm for different durations are shown in Fig. 1a. As illustrated, the diffraction peaks of the sample milled at 110 rpm for 1 hour could be indexed to the starting materials Li$_2$S, LiBr and P$_2$S$_5$. This step appears to be necessary in order to mix the raw materials homogeneously. After that, the milling speed was increased to 500 rpm to provide the mechanical energy necessary to obtain the Li$_6$PS$_5$Br phase. After 1 h of milling, the initially sharp diffraction peaks

The dotted lines represent fits using an equivalent circuit ($R_{\text{bulk}}Q_{\text{bulk}}$)($R_{\text{gb}}Q_{\text{gb}}$)Q. (c) The AC impedance results of Li$_6$PS$_5$Br (ball milled for 8 hours at 500 rpm) (blue), AN-Li$_6$PS$_5$Br (Li$_6$PS$_5$Br subsequently annealed at 300 °C for 5 hours) (red) and AN-BM-Li$_6$PS$_5$Br (AN-Li$_6$PS$_5$Br subsequently ball milled for 4 hours at 450 rpm) (pink). The dotted lines represent fits using an equivalent circuit ($R_{\text{bulk}}Q_{\text{bulk}}$)($R_{\text{gb}}Q_{\text{gb}}$)Q.
originating from the Li$_3$S phase broadened, indicating a decrease in particle size. Moreover, a halo pattern located in the low 2θ region appeared, indicating the formation of an amorphous phase.\textsuperscript{24} As the milling duration increases, diffraction peaks at 25.2, 29.7, 31.1 and 51.9° appear which can be attributed to the Li$_6$PS$_5$Br phase. Compared to the pattern measured after 1 h of milling, the intensity of the Li$_3$S diffraction peaks decreases and after a milling time of 10 h, the diffraction peak due to Li$_3$S located at 53.3° disappears completely.

The influence of the milling time on the Li-ion conductivity is investigated by impedance spectroscopy. The resistance of the mixture decreases sharply with increasing milling duration until a constant value is obtained after 8 h of milling, as shown in Fig. 1b. The increase in Li$^+$ conductivity during the milling process is associated with the concurrent decrease of the poorly conducting Li$_3$S phase and the increase of the Li-ion conducting Li$_2$S phase in the mixture. Because the material obtained after 8 hours reaches the maximum conductivity, this material is used for further investigations and referred to as Li$_6$PS$_5$Br.

Subsequently, this material is annealed at 300 °C for 5 h and the resulting material is referred to as AN-Li$_6$PS$_5$Br. Finally, the AN-Li$_6$PS$_5$Br is ball-milled at a rotation speed of 450 rpm for 4 hours, the resulting material of which is referred to as AN-BM-Li$_6$PS$_5$Br. The AC impedance and fitting results of the Li$_6$PS$_5$Br, AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br samples are shown in Fig. 1c. These result in bulk and grain boundary resistances of (924.8 ± 16.58) and (3.02 ± 0.64) × 10$^6$ Ω for Li$_6$PS$_5$Br, (516.8 ± 32.28) and (619.9 ± 22.26) Ω for AN-Li$_6$PS$_5$Br and (381.7 ± 10.81) and (686.8 ± 35.88) Ω for AN-BM-Li$_6$PS$_5$Br. The corresponding room temperature bulk conductivities are 6.20 × 10$^{-4}$ S cm$^{-1}$, 1.11 × 10$^{-3}$ S cm$^{-1}$ and 1.38 × 10$^{-3}$ S cm$^{-1}$ for Li$_6$PS$_5$Br AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br respectively. The annealing process increases the conductivity significantly and the subsequent ball milling step appears to further increase the bulk conductivity. Annealing dramatically lowers the grain boundary resistance as observed by impedance spectroscopy, whereas the subsequent ball milling process results in a small increase of the grain boundary resistance. Perhaps the most surprising result is that the bulk conductivity of AN-BM-Li$_6$PS$_5$Br is larger than that of the AN-Li$_6$PS$_5$Br, suggesting that decreasing the particle size of AN-Li$_6$PS$_5$Br enhances the Li-ion bulk conductivity. However, it should be realized that for these geometrically complex systems it is difficult to distinguish the bulk conductivity from the grain boundary resistance using impedance spectroscopy.

Both powder neutron and X-ray diffraction were performed, the data of which were simultaneously refined in the cubic F$\bar{4}3$m space group using the Rietveld method as implemented in GSAS.\textsuperscript{23} The neutron powder patterns and the X-ray patterns of the three Li$_6$PS$_5$Br materials are shown in Fig. 2 and the crystallographic parameters resulting from the refinements are provided in Table S1 of the ESI.\footnote{The smaller line width of the reflections of the AN-Li$_6$PS$_5$Br material in Fig. 2(c and d) compared to that of Li$_6$PS$_5$Br in Fig. 2(a and b) indicates an increase in crystallinity and crystallite size upon annealing. From the refinement of the patterns, assuming only size broadening, the average crystallite size of the Li$_6$PS$_5$Br material is 15 nm and of the AN-Li$_6$PS$_5$Br material is 74 nm. As shown in Fig. 2(c and f), subsequent ball milling of AN-Li$_6$PS$_5$Br resulting in the AN-BM-Li$_6$PS$_5$Br material increases the width of the reflections again, leading to an average crystallite size of 22 nm from the refinement. The substantial background observed in the diffraction pattern of Li$_6$PS$_5$Br, especially visible at low angles in Fig. 2a, indicates the presence of a significant amorphous fraction. The much lower background in Fig. 2c indicates that, as expected based on the glass temperature of 265 °C, annealing the sample at 300 °C converts most of the amorphous fraction to the crystalline Li$_6$PS$_5$Br phase. For the AN-BM-Li$_6$PS$_5$Br material, the background increases again, suggesting that the final ball milling procedure increases the amorphous fraction again. However, the larger lattice parameters of the AN-BM-Li$_6$PS$_5$Br material compared to that of the Li$_6$PS$_5$Br material and the smaller background suggest that the crystalline fraction of the AN-BM-Li$_6$PS$_5$Br material is larger than that of the Li$_6$PS$_5$Br material, which is also confirmed by the TEM experiments discussed in the next paragraph.}

The simultaneous refinement of the X-ray and neutron diffraction data allows us to determine the average amount of Br and S on the 4a (0,0,0) and 4c (0.25,0.25,0.25) crystallographic sites. Similar to what was found for Li$_6$PS$_5$Cl argyrodite,\textsuperscript{21} there is a slight preference for Br to occupy the 4c site as shown in Table S1 of the ESI.\footnote{The Br$_{4a}$ occupancy for AN-Li$_6$PS$_5$Br in Fig. 2(a and b) indicates that the Br$_{4c}$ occupancy in the amorphous phase of the Li$_6$PS$_5$Br sample, which turns crystalline upon annealing, is larger compared to the crystalline fraction of the Li$_6$PS$_5$Br sample. Vice versa the Br$_{4a}$ occupancy decreases upon annealing, keeping the total Br content close to the intended Li$_6$PS$_5$Br composition. Hence these results indicate that, although the Br appears to be homogeneously distributed throughout the particles, the relative 4a/4c site occupancy is inhomogeneous throughout the particles.}

Therefore, the suggested inhomogeneous site distribution of the Br dopant in the present argyrodite materials is likely to result in an inhomogeneous Li-ion conductivity, control over which may be an important parameter for the design of optimal solid electrolytes.
Fig. 3a and c show the bright-field TEM (BF-TEM) images of the Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br samples respectively and Fig. 3b and d show the electron diffraction patterns of Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br samples, acquired from the particles shown in 3a and 3c respectively. The presence of a ring-like diffraction pattern for the Li$_6$PS$_5$Br sample, without distinct diffraction spots, indicates the presence of a significant fraction of the amorphous material. After subsequent annealing and ball milling, the diffraction spots for AN-BM-Li$_6$PS$_5$Br become more distinct, indicating that the material becomes more crystalline, as shown in Fig. 3d. The Scanning Tunnel Microscope-Energy Dispersive X-ray (STEM-EDX) mapping of the Li$_6$PS$_5$Br sample (Fig. 3f) shows a homogeneous distribution of S, P and Br, indicating that this mechanical milling route is an effective synthesis method to prepare Li$_6$PS$_5$Br. Since the AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br are prepared starting from the Li$_6$PS$_5$Br sample with subsequent annealing and ball-milling processes, the S, P and Br in those samples are also expected to remain homogeneously distributed. SEM images displayed in Fig. S2 of the ESI† shows an interconnected platelet like structure for the Li$_6$PS$_5$Br and AN-Li$_6$PS$_5$Br materials, whereas the final ball milling step destroys this morphology resulting in
line width than that of Li_iPS_3Br, at 173 K, suggesting that a larger fraction of mobile Li-ions is present in the AN-Li_iPS_3Br material. The AN-BM-Li_iPS_3Br material has a larger line width than AN-Li_iPS_3Br and narrower line width than Li_iPS_3Br. A contributing factor towards the broader lines observed for both the ball-milled samples may also be the decreased crystallinity of both the Li_iPS_3Br and AN-BM-Li_iPS_3Br samples. This potentially results in a distribution of chemical shifts, induced by the high energy ball-milling. Interestingly, comparing AN-Li_iPS_3Br to previously studied Li_iPS_3Cl, the Li_iPS_3Br 7Li NMR resonance is shifted up-field to approximately -3 ppm. This is most likely caused by the increased shielding of the Li-ions by the neighboring Br dopants. The motional narrowing curves of Li_iPS_3Br, AN-Li_iPS_3Br, and AN-BM-Li_iPS_3Br measured versus temperature (see Fig. 4d) are in good agreement with that published by Epp and co-workers for the Li_iPS_3Br material. Epp et al. measured NMR spectra at 13 K and obtained an onset temperature for the Li-ion mobility of 87 K. Because of the temperature limitations of the instrument utilized for the present investigation, the measurements do not reach the so-called rigid-lattice regime where Li-ion hopping is frozen. Above room temperature, the line shape can be deconvoluted into a narrow Lorentzian and a broad Gaussian which are assigned to mobile and static Li-ion populations respectively (see ESI Fig. S1†). This allows us to evaluate the fraction of mobile Li-ions (A_i) in Li_iPS_3Br, AN-Li_iPS_3Br and AN-BM-Li_iPS_3Br as a function of temperature, as shown in the inset of Fig. 4d. At 183 K, an A_i value of 25% was determined for Li_iPS_3Br, while that for AN-Li_iPS_3Br and AN-BM-Li_iPS_3Br is approximately 50%, indicating that annealing increases the amount of mobile Li-ions significantly.

To quantitatively determine the local Li-ion temperature-dependent mobility, 7Li static spin–lattice relaxation (SLR) rates in the laboratory frame, 1/T_1, and in the rotating frame 1/T_1(o) are measured, the results of which are shown in Fig. 5. Provided that the variation of the SLR is only induced by Li-ion mobility, the temperature dependence of the SLR rate in the laboratory frame, 1/T_1, can be used to quantify the Li-ion jump frequency and the corresponding activation energy. The longer range ionic motion taking place at a larger time scale can be probed by SLR NMR measurements in the rotating frame. The hopping frequency 1/τ, where τ is the residence time, is assumed to be equal to the correlation time between hops. When 1/T_1(o) reaches a maximum as a function of temperature, the hopping frequency 1/τ is in the order of the Larmor frequency (ω_o) or spin lock frequency (ω_u). In the laboratory frame, the longitudinal relaxation rate 1/T_1 reaches a maximum near ω_o^2 τ_e^2 ≈ 1, a consequence of the effective energy transfer between the system with the diffusing atoms. The maximum relaxation rate 1/T_1 is reached at 383 for Li_iPS_3Br and 358 K for both AN-Li_iPS_3Br and AN-BM-Li_iPS_3Br. With a Larmor frequency of ω_o/2π = 155.506 MHz, the Li-ion jump frequency 1/τ_e for the Li_iPS_3Br (at 383 K) and for AN-Li_iPS_3Br and AN-BM-Li_iPS_3Br (at 358 K) can be determined to be approximately 9.8 10^8 s^-1, similar to what was reported previously for Li_iPS_3Br. Because this jump rate is achieved at a lower temperature for both AN-Li_iPS_3Br and AN-BM-Li_iPS_3Br,
distribution over the 4a and 4c sites. The SLR rates, 1/mobility may be from the larger crystallinity and/or the Br NMR resonance with temperature for Li6PS5Br, AN-Li6PS5Br and AN-BM-Li6PS5Br. The inset shows the fraction of the mobile Li-ions in the three materials.

The Larmor frequency is 155.506 MHz (lock frequency is 20 kHz) versus materials. The original BPP behaviour does not take into account correlation effects and disorder in diffusional processes. The Li-ion residence time, \( t_{\text{ff}} \), is directly related to the spectral density functions of the Li-ion jumping processes. The activation energy for the lithium jump rate is predicted symmetric (with \( 1 < \beta \approx 2 \)).

The asymmetry, quantified by \( \beta = 1.73, 1.78 \) and \( 1.67 \) for Li6PS5Br, AN-Li6PS5Br and AN-BM-Li6PS5Br, is slightly higher than the previous results reported for annealed Li6PS5Br probed by temperature dependent SLR NMR (1/\( T_{1} \) and 1/\( T_{1p} \)).

The low temperature flank represents a short range motional process whereas the high temperature flank most likely represents longer range Li-ion resulting in actual diffusion. The activation energies for all three Li6PS5Br in the high temperature flank are close to that deduced by temperature-dependent ionic conductivity measurements reported by Rayavarapu et al. i.e. 0.17 eV from 300 to 600 K, and are slightly smaller in comparison with the 0.2 eV reported by Epp et al. The activation energy for three Li6PS5Br samples in the low temperature flank, representing local motional processes, is approximately 0.1 eV, which is comparable to the values for the 48h–48 h and intra-cage local Li-ion motional processes predicted by MD simulations for Li6PS5Br. This suggests that the 1/\( T_{1} \) rates in the low temperature flank reflect local Li-ion movement inside Li6PS5Br similar to what was found for Li6PS5Cl.

The 7Li SLR measurements in the rotating frame (1/\( T_{1p} \)), also shown in Fig. 5, were performed to probe Li-ion mobility on a larger length and time scale in all three Li6PS5Br materials to complement the local hopping probed by 1/\( T_{1} \) relaxation. In the rotating frame at a lock frequency \( v_{\text{lock}} \), the maximum condition for the lithium jump rate is \( v_{\text{lock}}^T = 0.5 \). The corresponding jump rates in this rotating frame (lock frequency 20 kHz) are the same, 2.512 \( \times 10^{5} \) s\(^{-1} \) at 228 K for the three Li6PS5Br materials. This indicates that the time scale of Li-ion diffusion on a longer length scale (several hops) is comparable for all three materials. However, the activation energies for the high temperature flank of the 1/\( T_{1p} \) rates, observed in Fig. 5, are considerably higher at 0.33–0.34 eV, in comparison with the
0.14–0.15 eV of the high temperature flank of the $1/T_1$ relaxation rates. The larger diffusion time probed by the measurement in the rotating frame suggests that not only the local bulk kinetics are probed, but also Li-ion diffusion through grain boundaries is observed. The slightly smaller activation energies of the AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br materials deduced from the $1/T_1\rho$ rates in the high temperature flank suggest that the annealing process promotes Li-motion in Li$_6$PS$_5$Br over longer length scales. This could suggest better mobility over grain boundaries, consistent with the lower grain boundary resistances observed for these materials with room temperature impedance spectroscopy, Fig. 1c. In summary, the $^7\text{Li}$ NMR relaxation experiments indicate slightly improved Li-ion mobility for the annealed materials both for local Li-ion hopping, and longer range diffusion, although the activation energies are very similar. The much higher activation energy for the long range diffusion, as observed from the spin-locked SRL experiments, suggests that these experiments probe the Li-ion diffusion over grain boundaries.

**Electrochemical performance**

When combining a cathode material with a solid electrolyte, it is essential to investigate the chemical and electrochemical stability. Nano-Li$_2$S was selected as the cathode material for this study and the stability and conductivity of the cathode mixture with the AN-Li$_6$PS$_5$Br solid electrolyte were investigated by cyclic voltammetry (CV), powder XRD and AC impedance spectroscopy, the results of which are shown in ESI Fig. S4 and S5.$^\dagger$ In the diffraction patterns of the Li$_2$S and AN-Li$_6$PS$_5$Br mixture before and after milling and annealing, no additional diffraction peaks are detected, suggesting that nano-Li$_2$S is stable with the annealed Li$_6$PS$_5$Br solid electrolyte up to 180 °C. Another important factor to consider is the overall conductivity of the cathode–electrolyte mixture,$^{36,37}$ which for the present mixture resulted in a resistance of 750 Ω yielding a Li$^+$ conductivity of $\sim$10$^{-4}$ S cm$^{-1}$, indicating that this nano-Li$_2$S–Li$_6$PS$_5$Br cathode mixture is a viable solid-state electrode. Initially, it has been suggested that sulfide solid electrolytes, including the presently investigated argyrodite Li$_6$PS$_5$Br, have a very wide electrochemical stability window. However, recent calculations$^{36,39}$ and experimental observations indicate otherwise.$^{40–42}$ The performance of the all-solid-state batteries will depend on the formation of oxidation and/or reduction products at the interfaces between the electrode material and the solid electrolyte, and to what extent this hinders Li-ion transport. Previous results$^{36,37}$ on the chloride doped argyrodite Li$_6$PS$_5$Cl solid electrolyte have shown that the (dis)charge voltage window has a significant influence on the electrochemical performances of these solid-state batteries. At present, the optimal (dis)charge voltage window was determined for the nano-Li$_2$S/AN-Li$_6$PS$_5$Br/In solid-state batteries by systematic variation of the voltage window for cyclic voltammetry (CV) measurements, as shown in Fig. S5 of the ESI.$^\dagger$ This indicates that, to obtain the highest apparent coulombic efficiency, the optimum charge/discharge window for this assembled nano-Li$_2$S/AN-Li$_6$PS$_5$Br/In solid-state cell is between 0 and 3.5 V vs. Li/Li$^+$. The finding that the higher cutoff voltage during charge (i.e. 4.0 V vs. In) results in a lower coulombic efficiency, compared to the optimal cutoff (3.5 V vs. In), is most likely the result of more severe oxidation of the solid electrolyte, in line with the limited electrochemical stability obtained by thermodynamic predictions$^{38,39}$ and experimental analysis after charging of Li$_6$PS$_5$Br in positive electrode mixtures.$^{41}$

To investigate the impact of annealing and subsequent ball milling treatment on the solid-state battery performance, cathodic mixtures of the nano-Li$_2$S cathode were prepared with the Li$_6$PS$_5$Br, AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br solid electrolyte materials. In Fig. 6a, the first 4 charge/discharge curves are compared at the same current density of 0.064 mA cm$^{-2}$ in the earlier determined optimal voltage window of 0–3.5 V vs. In (0.62–4.12 V vs. Li$^+$/Li). The differences in capacity retention are striking, where the solid-state cell using AN-BM-Li$_6$PS$_5$Br shows a significantly better electrochemical performance when compared to that for both the AN-Li$_6$PS$_5$Br and Li$_6$PS$_5$Br solid electrolyte materials. For the solid-state cell using Li$_6$PS$_5$Br as the electrolyte, the (dis)charge curves during the first four cycles show no obvious (dis)charge plateau and a very low discharge capacity, smaller than 50 mA h g$^{-1}$. In contrast, the charge curves of the solid-state cells with the AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br solid electrolytes deliver two distinct charge plateaus, located at 1.8 and 2.3 V vs. In, respectively and a discharge plateau located at approximately 1.4 V vs. In. Although the AN-Li$_6$PS$_5$Br solid-state cell results in a promising initial discharge capacity, it degrades to below 400 mA h g$^{-1}$ within a few cycles. The best capacity retention is achieved with the AN-BM-Li$_6$PS$_5$Br solid electrolyte, resulting in a capacity of approximately 500 mA h g$^{-1}$ retained over 25 cycles. The initial discharge capacity is comparable to that demonstrated by Li$_2$S cathodes in combination with organic liquid electrolytes, which is reported to be 785 mA h g$^{-1}$ at a higher rate i.e. 0.2C.$^{44}$ The present solid-state cell provides a higher discharge capacity and better cyclability compared to most reported comparable solid-state cells employing composite Li$_2$S electrodes in combination with argyrodite and 80Li$_2$S–20P$_2$S$_5$ solid electrolytes.$^{38,39}$ However, the electrochemical performance reported in this work is not as good as that for the solid-state cell in combination with a mixed-conductive Li$_2$S nanocomposite cathode and Li$_6$PS$_5$Cl electrolyte$^{45}$ most likely due to the better distribution of Li$_2$S, Li$_6$PS$_5$Cl and carbon in the cathode mixture.

During the first 5 cycles, the discharge capacity increases per cycle, which is attributed to the activation process for the Li$_2$S cathode mixture. However, a higher charge capacity than discharge capacity is observed over many cycles. This may indicate that not only the Li$_2$S cathode is oxidized but also the Li$_6$PS$_5$Br electrolyte at the interface with the Li$_2$S may be oxidized. Calculations indicate a very narrow stability window for argyrodite Li$_6$PS$_5$Cl,$^{38,39}$ resulting in S, P$_2$S$_5$ and LiCl oxidation products above 2.3 V vs. Li/Li$^+$. For Li$_6$PS$_5$Br at the Li$_2$S interface, this suggests that cycling up to 4.12 V vs. Li/Li$^+$ during charge leads to the formation of S, P$_2$S$_5$ and LiBr in the present cells, potentially explaining the larger charge capacity observed during cycling. It should be noted that this potentially increases the amount of S in the cell, acting as a positive electrode.
material that may participate in subsequent (dis)charge cycles. This demonstrates a compromise made in using a large cut-off potential during charge. The large cut-off potential is necessary to overcome the large internal resistance, most likely dominated by the Li$_6$PS$_5$Br–Li$_2$S interface, and utilize the Li$_2$S capacity. At the same time, this initiates the oxidation of the Li$_6$PS$_5$Br solid electrolyte. This suggests that the poor capacity retention of the AN-Li$_6$PS$_5$Br material, shown in Fig. 6b, is related to the larger overpotentials during charge and discharge, observed in Fig. 6a, causing more severe electrolyte decomposition. As the bulk and grain boundary conductivities of the AN-Li$_6$PS$_5$Br and AN-BM-Li$_6$PS$_5$Br do not differ very much, which was concluded from impedance spectroscopy and the solid state NMR relaxation experiments, the larger overpotentials of the AN-Li$_6$PS$_5$Br material must be the consequence of the larger crystallite size providing a smaller interfacial area with the Li$_2$S cathode and hence causing a larger interfacial resistance. Fig. 6c shows the corresponding coulombic efficiency of the assembled nano-Li$_2$S/Li$_6$PS$_5$Br (Li$_6$PS$_5$Br or AN-Li$_6$PS$_5$Br or AN-BM-Li$_6$PS$_5$Br)/In solid-state batteries. The coulombic efficiency is defined as the ratio of discharge capacity to charge capacity.

In contrast, the larger interfacial area provided by the AN-BM-Li$_6$PS$_5$Br material results in lower overpotentials. This appears to cause the stabilization of the Li$_6$PS$_5$Br, as the differences of (dis)charge capacity in Fig. 6 become smaller upon cycling. Hence, despite the suggested formation of an oxidation layer at the Li$_6$PS$_5$Br–Li$_2$S interface, as well as the large volumetric changes that occur upon Li$_2$S oxidation, these solid-state cells provide a relatively constant capacity retention, at least up to 25 cycles.

Conclusions

The impedance spectra in Fig. 1c indicate a significant increase in the bulk conductivity upon annealing the Li$_6$PS$_5$Br material (AN-Li$_6$PS$_5$Br) prepared by ball milling. The NMR relaxation experiments in Fig. 4 and 5 show that the bulk Li-ion mobility is only marginally improved, and that the increase in conductivity should be mainly attributed to the larger fraction of mobile Li-
ions. This increase is most likely due to the presence of the increased crystalline fraction shown by XRD and TEM in Fig. 2 and 3, which is known to display a better mobility. Additionally, the simultaneous refinements of the neutron and X-ray diffraction data suggest that the conductivity may be inhomogeneous due to differences in the Br dopant distribution throughout the Li6PS5Br particles. Although the Br dopant appears to be homogeneously distributed over the material, it is not homogeneously distributed over the two crystallographic sites. For the annealed materials, AN-Li6PS5Br and AN-BM-Li6PS5Br, the site distribution appears to be more favorable for a high conductivity in the crystalline fraction that forms due to the annealing process. An interesting future research direction may be to investigate the role of these distributions on solid-state battery performance, and synthesis routes to control the site distribution of the halogen dopant.

Annealing lowers the grain boundary resistance dramatically, whereas subsequent ball milling results in a slight increase in grain boundary resistance. Compared to the T1 NMR relaxation experiments, the T1p experiments probe a longer diffusion length scale. The much larger activation energy deduced from the T1p experiments suggests that this includes diffusion across grain boundaries. However, these larger activation energies changed only marginally with the annealing and the ball milling treatment, suggesting that this does not change the Li-ion dynamics across the grain boundary regions. This also suggests that at the Li6PS5Br–Li2S interfaces, a larger crystalline fraction is beneficial for the conductivity, most likely increasing the fraction of mobile ions at the interface, rather than the mobility itself. Additionally, we anticipate that the inhomogeneous distribution of Br over the two crystallographic sites may be at least partially responsible for the larger Li-ion mobility at the interfaces.

Both impedance spectroscopy and NMR experiments indicate a very similar bulk and grain boundary Li-ion mobility for the annealed (AN-Li6PS5Br average crystallite size 74 nm) and additionally ball milled (AN-BM-Li6PS5Br average crystallite size 22 nm) materials. However, the solid-state battery with the AN-BM-Li6PS5Br electrolyte provides much better capacity retention upon cycling. The smaller particles of the annealed and ball milled material, AN-BM-Li6PS5Br, appear essential for stable capacity retention, most likely through the establishment of more abundant interfacial contacts with the Li2S cathode resulting from the higher surface area of the small solid electrolyte particles, lowering the interfacial resistance. These results indicate a different demand for the solid electrolyte in the solid electrolyte region of the cell compared to the solid electrolyte in the cathode mixture. In the solid electrolyte region, the lowest overall resistance dominated by the grain boundary resistance is achieved for the annealed material (AN-Li6PS5Br), whereas smaller solid electrolyte particle sizes are required to provide sufficient solid electrolyte–cathode interfaces, to minimize the resistance of this rate limiting Li-ion transport step.

In conclusion, the internal resistance of the solid electrolyte is dominated by the solid electrolyte–solid electrolyte Li6PS5Br interfaces, lowering of which can be achieved by annealing treatment. The results indicate that an inhomogeneous distribution of the Br dopant over the crystallite sites may play an important role in the conductivity at the interfaces. The largest contributor to the internal resistance of the Li6S/Li6PS5Br solid–state battery appears to exist at the Li6PS5Br/Li6S interface. To utilize a majority of the Li6S capacity, a large overpotential is required, even at the low currents. This compromises the electrochemical stability of the Li6PS5Br solid electrolyte, most likely leading to oxidation products. Despite the electrochemical instability at the Li6PS5Br/Li6S interface and the large volumetric changes upon charging Li6S, the capacity retention of this all-solid-state battery is promising, most likely because of the abundant Li6PS5Br/Li6S interfaces that provide sufficient Li-ion conductivity and the large fraction of Li6PS5Br in the positive electrode mixture. Evidently, the improvement of these solid-state battery systems requires focusing on the stabilization of the solid electrolyte–electrode interfaces, to prevent both electrochemical instabilities and volumetric changes. Additionally, the present results indicate the importance of inhomogeneity in the conductivity and the importance of distinguishing between the electrolyte properties only in the electrolyte region and the electrolyte in the cathode mixture.
