The aim of the study was to examine the oral health status of Parkinson’s disease (PD) patients, to compare their oral health status to that of a control group, and to relate it to the duration and severity of PD. Materials and Methods. 74 PD patients and 74 controls were interviewed and orally examined. Among PD patients, the duration and the Hoehn and Yahr stage (HY) of the disease were registered. Results. More PD patients than controls reported oral hygiene care support as well as chewing/biting problems, taste disturbance, tooth mobility, and xerostomia, whereas dentate patients had more teeth with carious lesions, tooth root remnants, and biofilm. Both longer duration and higher HY were associated with more chewing problems and, in dentates, more teeth with restorations. In dentates, longer duration of the disease was associated with higher number of mobile teeth. Higher HY was associated with more oral hygiene care support as well as biting problems and, in dentates, more teeth with carious lesions and tooth root remnants. Conclusions. Comparatively, PD patients had weakened oral health status and reduced oral hygiene care. Both duration and severity of the disease were associated with more oral health and hygiene care problems.

1. Introduction

Parkinson’s disease is a progressive degenerative neurological disorder, characterized by motor and nonmotor symptoms. The motor symptoms include akinesia, bradykinesia, rigidity, and tremor, which remain not restricted to the trunk and extremities, but may also occur in the orofacial system [1–3]. Motor impairments of the orofacial system include dysphagia, masticatory dysfunction, orofacial dyskinesia, and oromandibular dystonia [4–7]. In addition, related to oral health, the potentially impaired dexterity of arms and fingers may hamper the required daily oral hygiene care [8].

Advances in oral health care and treatment during the past few decades have resulted in a reduced number of edentulous individuals. The proportion of adults who retain their teeth until late in life has increased substantially [9]. Consequently, a still increasing number of dentate older people experience oral health problems, such as dental caries, periodontal disease, and substantial wear of hard tooth tissues (tooth wear). Furthermore, many older people have been treated with oral implants and/or sophisticated tooth- and/or implant-supported fixed and/or removable dental prostheses. Hence, these older people are in continuous need of both preventive and curative oral health care. The complexity of oral health status, the potential presence of systemic diseases, and the use of several medications make older people more vulnerable to oral problems when compared to younger age groups, particularly in those who are cognitively impaired [10, 11]. In addition, weakened oral health due to neglected oral hygiene care and reduced oral health care utilization has previously been found in older people [11–14].

Oral diseases, such as dental caries and periodontal disease, not only have oral effects, for example oral pain and oral functioning problems, but may also impact a number of systemic conditions. Emerging evidence suggests that poor oral health influences the initiation and/or progression of
2. Materials and Methods

2.1. Study Population. The current cross-sectional, case-control, optimally gender-, age-, social background-, and lifestyle-matched study was approved by the Medical Ethical Committee of Leiden University Medical Center, Leiden, the Netherlands, approval number P13.079. Assuming a power (1-β) of 0.80 and an α of 0.05 and an objective to detect a prevalence difference of 25% between groups across a range of different hypothetical prevalence rates, a sample size calculation indicated that 69 persons per group of Parkinson’s disease patients and control subjects would be sufficient.

Patients with Parkinson’s disease, without severe comorbidity according to classes III and IV of the Physical Status Classification System of the American Society of Anesthesiologists, were requested to participate when they visited the Department of Neurology of the Leiden University Medical Center, Leiden, the Netherlands, for a routine periodic consultation. The Parkinson’s disease patients who agreed to participate, were subsequently requested to identify a control person, for instance a family member or other close relative, who had no Parkinson’s disease or other severe systemic diseases according to classes III and IV of the Physical Status Classification System of the American Society of Anesthesiologists, who had approximately the same age (±5 years) as well as a similar social background and lifestyle, and who would likely be prepared to participate. The group of control subjects was also optimally gender matched, meaning that men with Parkinson’s disease preferably indicated men and women with Parkinson’s disease preferably indicated women. Assuming that not every person proposed by a Parkinson’s disease patient as control subject would agree to participate, initially 74 Parkinson’s disease patients were included. All Parkinson’s disease patients and indicated control subjects were visited at their homes to inform them about the research project. Luckily, all of them provided informed consent and were subsequently interviewed and examined.

After the interview and the examination, every participant received information on his/her actual oral health condition and was recommended consultation with a dentist in case the actual oral health condition required attention and/or treatment.

2.2. Assessments. Using a common history form, data were gathered about educational level (primary, secondary, and tertiary), smoking habits, length of time since the last oral health consultation, number of oral health consultations during the previous five years, daily oral hygiene care (whether or not supported by a professional or voluntary care provider), type of toothbrush used, chewing problems, biting problems, taste disturbance, burning mouth, xerostomia, halitosis, remaining food particles, tooth mobility, toothache, tooth sensitivity, painful gums, and bleeding gums. Persons with an edentulous maxilla/mandible were requested to indicate the duration since the last teeth in the maxilla/mandible had been removed, the number of years during which a current complete maxillary/mandibular removable dental prosthesis was functioning, and their potential experience with a loose coming complete maxillary/mandibular removable dental prosthesis during oral movements.

An experienced dentist performed an oral health examination in all participants, using a common oral screening form. Variables included were edentulousness, soft tissue lesions, complete or partial maxillary/mandibular removable dental prostheses, number of teeth, number of teeth with carious lesions, number of teeth with restorations, number of tooth root remnants, amount of biofilm and food, periodontal health, and number of posterior functional tooth units, including (implant-supported) single- and multunit fixed dental prostheses.

The amount of biofilm and food on teeth and soft tissues was assessed by a simple 3-points scale: 1 = hardly any biofilm and food; 2 = thin layer of biofilm and food; 3 = thick layer of biofilm and food.

Periodontal health was assessed using the tooth mobility scoring system. This clinically easy-to-determine system differentiates three grades: grade I: mobility in a horizontal direction more than 0.2 mm and less than 1 mm; grade II: mobility in a horizontal direction of 1 mm or more; and grade III: mobility in vertical direction [29].

The number of posterior functional tooth units is an important proxy for masticatory efficiency. One maxillary and one mandibular premolar in occluding contact constitute one posterior functional tooth unit. One occluding maxillary and mandibular molar are equivalent to two posterior functional tooth units [30].

In persons with an edentulous maxilla/mandible, the reduction of the edentulous residual alveolar ridge was clinically classified as moderate reduction, high degree of reduction, or extensive reduction, using a standard set of edentulous alveolar ridge models [31].
For Parkinson’s disease patients, the duration of the disease (since the onset of motor symptoms) and the severity of the disease expressed by the Hoehn and Yahr stage were registered from the patients’ medical records [32]. The duration of the disease was categorized as less than 5 years, between 5 and 9 years, and 10 years or longer.

</table>

ordinal or nonnormally distributed continuous variables between groups. Kruskal–Wallis test was used to examine group differences of nonnormally distributed continuous variables with three or more categories. Statistical significance was accepted at $P < 0.05$. Given the exploratory character of the study, no attempt was made to control for multiple comparisons.

### 3. Results

#### 3.1. Participants

Interviews and oral health examinations were performed in 26 women and 48 men with Parkinson’s disease and in 35 female and 39 male control subjects ($\chi^2_{(1)} = 2.259, P = 0.133$). Mean age ± standard deviation was 70.2 ± 8.8 years in the Parkinson’s disease patients and 67.9 ± 10.1 years in the control subjects (Student’s t-test; $P = 0.641$).

#### 3.2. Subjective Variables

Table 2 presents frequencies and percentages of the subjective variables of the Parkinson’s disease patients and the control subjects. When compared to the control subjects, statistically significantly more Parkinson’s disease patients reported daily oral hygiene care support by a professional or voluntary care provider, chewing problems, biting problems, taste disturbance, and xerostomia. When compared to the dentate control subjects, statistically significantly more dentate Parkinson’s disease patients reported tooth mobility.

The Parkinson’s disease patients and control subjects with an edentulous maxilla (and mandible) showed no statistically significant group differences with regard to length of time since the last teeth had been removed, number of years during which a current complete maxillary/mandibular removable dental prosthesis was functioning, and persons’ experiences with a loose coming complete maxillary/mandibular removable dental prosthesis during oral movements.

#### 3.3. Objective Variables

Table 3 presents frequencies and percentages of the objective variables of the Parkinson’s disease patients and the control subjects. Statistical analysis of the data of dentate persons did point out that the
Parkinson’s disease patients had statistically significantly more teeth with carious lesions, a greater number of tooth root remnants, and a greater amount of biofilm and food when compared to the control subjects.

Only few Parkinson’s disease patients and control subjects had teeth with grades II and III of tooth mobility, 11 and 6 persons, respectively. Therefore, comparisons of periodontal health between Parkinson’s disease patients and control subjects were not performed.

The persons who had an edentulous maxilla/mandible, showed no statistically significant differences between Parkinson’s disease patients and control subjects with regard to grades of reduction of the edentulous residual alveolar ridges.

### 3.4. Parkinson’s Disease Patients

The distribution of the Parkinson’s disease patients across duration and Hoehn and Yahr stage of the disease is presented in Table 4.

The mean duration of the disease was 9.1 ± 6.4 years. Reported chewing problems were statistically significantly positively related to the duration of the disease ($\chi^2(4) = 17.690$, $P = 0.024$). In dentate patients, the number of teeth with restorations and the number of teeth with mobility grade II or III were statistically significantly related to the duration of the disease (Kruskal–Wallis test; resp. $H(2) = 6.398$, $P = 0.041$ and $H(2) = 8.058$, $P = 0.018$).

For subsequent statistical analysis, the Hoehn and Yahr stages were dichotomized, resulting in a group of 47 patients with the mild stages 1 and 2 and a group of 27 patients with the moderate/severe stages 3, 4, and 5. The reported chewing and biting problems as well as the reported daily support for oral hygiene care by a professional or voluntary care provider were statistically significantly positively related to the Hoehn and Yahr stage of the disease (resp. $\chi^2(4) = 14.045$, $P = 0.007$; $\chi^2(4) = 10.939$, $P = 0.027$; $\chi^2(1) = 11.457$, $P = 0.001$). Furthermore, the number of teeth with carious lesions, the number of teeth with restorations, and the number of tooth root remnants appeared statistically significantly higher in dentate patients with the moderate/severe Hoehn and Yahr stages 3–5, when compared to dentate patients with the mild Hoehn and Yahr stages 1–2 (Mann–Whitney $U$ test; resp., $U = 246.500$, $P = 0.001$; $U = 252.500$, $P = 0.004$; $U = 311.000$, $P = 0.002$).

### 4. Discussion

This is the first study which examined the most relevant aspects of the subjective as well as the objective oral health status of a large group of Parkinson’s disease patients, which compared these findings with the same data of an optimally gender-, age-, social background-, and lifestyle-matched control group and which related the oral health status of the Parkinson’s disease patients to the duration and severity of the disease. The findings demonstrate that more Parkinson’s disease patients than control subjects reported daily oral hygiene care support by a professional or voluntary care provider, as well as chewing problems, biting problems, taste disturbance, tooth mobility, and xerostomia. Objectively, the dentate Parkinson’s disease patients had a greater number of teeth with carious lesions, a greater number of teeth with restorations, and a greater number of tooth root remnants.
number of tooth root remnants, and a greater amount of biofilm and food, when compared to the dentate control subjects. These findings represent symptoms of weakened oral health and reduced oral hygiene care, probably due to Parkinson’s disease impairments. Within the group of Parkinson’s disease patients, both longer duration and higher Hoehn and Yahr stage of the disease were associated with more chewing problems and, in dentate persons, with more teeth with restorations. Additionally, in dentate persons, longer duration of the disease was associated with a higher number of teeth with mobility grade II or III, whereas a higher Hoehn and Yahr stage of the disease was associated with more daily oral hygiene care support by a care provider as well as biting problems and, in dentate persons, with more teeth with carious lesions and more tooth root remnants. These findings reflect symptoms of weakening oral health, probably due to the reducing ability to manage oral hygiene care as the disease advances.

Existing data on the oral health of Parkinson’s disease patients, as presented in Table 1, are extended by the results of the current study. Novel identified oral health problems include taste disturbance and more oral health problems in advanced stages of the disease. Together, these data indicate that weakening oral health and its potential negative impact on several systemic conditions are serious problems in Parkinson’s disease patients, which demand more attention worldwide by the multidisciplinary Parkinson’s disease medical management teams as well as standard referrals to oral health-care providers.

Chewing and biting problems, more reported by Parkinson’s disease patients than control subjects, predominantly in advanced stages of the disease, may reflect (increasing) motor impairments of the orofacial system. Consequently, it is recommended to consider research of chewing and biting problems in Parkinson’s disease patients with the objective to manage or reduce these problems. Other impairments of the orofacial system of Parkinson’s disease patients may present as temporomandibular dysfunction. A recent study among a group of Parkinson’s disease patients found temporomandibular dysfunction in about one-fifth of the patients [33]. Nevertheless, since diagnosing and classifying temporomandibular dysfunction is a rather complicated and time-consuming activity [34], we decided consciously not to include temporomandibular dysfunction as a research variable in our study. A separate and specific study on this topic is in preparation by the research groups involved in the current study.

When considered in relation to oral health, taste disturbance is certainly a novel finding in Parkinson’s disease patients since none of the studies mentioned in Table 1 reported this problem. However, olfactory loss as well as smell and taste loss are well-known neurological problems in Parkinson’s disease. Results of a recent (neurological) study suggest that the problems are caused by a decline of central brain networks rather than a damage of the peripheral olfactory system [35]. Previously, the olfactory deficit was demonstrated to be independent of Parkinson’s disease severity and duration and preceding clinical motor symptoms by years. For this reason, taste disturbance was even suggested to be used for assessing the risk of Parkinson’s disease in otherwise asymptomatic individuals [36]. From an oral health perspective, taste ability may change due to deterioration of oral health status, deficient oral hygiene, and impaired masticatory ability [37]. Additionally, saliva is of great importance since it acts as a solvent of taste substances, affects taste sensitivity, and maintains the health and function of the taste receptors. Consequently, hyposalivation results, among others, in significant altered taste sensation or taste disturbance [38]. Hyposalivation may induce oral health problems, such as tooth wear, oral soft tissue lesions, dental caries, candidiasis, and periodontal disease [39]. Nearly 65% of the Parkinson’s disease patients in our study reported xerostomia (Table 2), confirming previous results demonstrating or suggesting that xerostomia and the commonly underlying hyposalivation are prevalent complications of Parkinson’s disease [28, 40]. Another saliva complication of Parkinson’s disease patients is drooling. Most likely, impaired intraoral saliva clearance is the basis of its pathophysiology. However, research to explore the exact pathophysiology and to develop standard diagnostic criteria and assessment tools are needed [41]. Therefore, taste disturbance, xerostomia, hyposalivation, and drooling are topics challenging collaboration between movement disorders specialists and dentists.

Several results of the current study suggest a reduced ability to manage oral hygiene care due to Parkinson’s disease impairments, which increases as the disease advances. This assumption concurs with the finding of impaired dexterity in Parkinson’s disease, predominantly in advanced stages of the disease [8]. Furthermore, a recent study proved that fine motor skills in Parkinson’s disease patients are impaired, predominantly in patients with mild cognitive impairment [42]. Probably, at a certain, difficult to predict stage of Parkinson’s disease, patients become dependent on professional or voluntary care providers for proper daily oral hygiene care. In the current study, 15% of the Parkinson’s disease patients reported as such. Unfortunately, oral hygiene care is generally not prioritized, either by the professional care providers, or by the patients themselves. Even providing a guideline to nursing home care providers and supervised implementation of this guideline did not result in a general improvement of oral hygiene of nursing home residents [43]. Subsequently, it was recommended to better integrate professional oral hygiene care into professional general health care (also in Parkinson’s disease patients) in order to prevent poor oral health to become a new geriatric syndrome [44].

A retrospectively ascertained weakness of this study is the lack of data on social background and lifestyle of both the Parkinson’s disease patients and the control subjects. Although the patients were requested to identify a family member or other close relative who had a similar social background and lifestyle as a control person, these variables were not actually assessed. Therefore, some selection bias cannot be ruled out.

5. Conclusions

The results of the current study reveal that the Parkinson’s disease patients had a weakened oral health status and
reduced oral hygiene care, when compared to an optimally
gender-, age-, social background-, and lifestyle-matched
control group. Additionally, both longer duration of the
disease and more severe disease were associated with more
oral health and oral hygiene care problems, altogether
suggesting that their weakened oral health and reduced oral
hygiene care are due to Parkinson’s disease impairments.
The authors recommend worldwide multidisciplinary Par-
kinson’s disease medical management teams to pay more
attention to their patients’ oral health including standard
referrals to oral health-care providers, to establish research
of chewing and biting problems, taste disturbance, xero-
stomia, hyposalivation, and drooling in Parkinson’s disease
patients through collaboration of movement disorders
specialists and dentists, and to integrate professional oral
hygiene care into professional general health care for Par-
kinson’s disease patients.
