Abstract

Involvement of signal transducer and activator of transcription 3 (STAT3) in inflammation is well known. Recently, a role for STAT3 in platelet activation and platelet production has been suggested. Platelets exhibit important immune functions and engagement of STAT3 in platelet physiology may link inflammation and hemostasis. This study investigated the effects of STAT3 loss-of-function mutations and single nucleotide polymorphisms (SNPs) in STAT3 on glycoprotein VI (GPVI)-mediated platelet activation and platelet numbers in humans. Two cohorts were studied. The first cohort concerned patients with STAT3 loss-of-function mutations. Platelet numbers were investigated in eight patients and GPVI-mediated platelet activation was functionally tested in four patients. Additional experiments were performed to investigate underlying mechanisms. The second cohort concerned 334 healthy volunteers and investigated the consequences of SNPs in STAT3 on GPVI-mediated platelet activation and platelet numbers. Platelet activation was lower in STAT3 loss-of-function patients at baseline and after stimulation of the GPVI receptor, reflected by decreased P-selectin expression. This was independent of gene transcription. Blockade of the adenosine di-phosphate (ADP) pathway resulted in a further decrease of P-selectin expression, particularly in STAT3 loss-of-function patients. In contrast, the SNPs in STAT3 did not influence GPVI-mediated platelet activation. Also, platelet numbers were not affected by STAT3 loss-of-function mutations, nor was there an association with the SNPs. In conclusion, STAT3 signaling does not seem to play a major role in thrombopoiesis. We confirm that STAT3 is involved in GPVI-mediated platelet activation in humans, independent of gene transcription. GPVI-mediated platelet activation is highly dependent on secondary ADP release. Our findings suggest that STAT3 modulation may affect inflammation, hemostasis, and their interaction.

Introduction

28 September 2017 STAT3 was shown to play a role in platelet activation [9–11] and in thrombopoiesis [12]. Zhou and colleagues reported that platelet activation via surface receptor glycoprotein VI (GPVI) is impaired in platelet STAT3-knockout mice [9]. Additionally, \textit{ex vivo} STAT3 inhibition by pharmacological inhibitors resulted in decreased platelet activation and less thrombus formation after stimulation of GPVI with platelet agonist collagen-related peptide (CRP) in humans [9]. Grozovsky and colleagues showed involvement of STAT3 in platelet production [12]. Binding of desialylated platelets to the Ashwell–Morell receptor induced hepatic thrombopoietin (TPO) via a mechanism dependent on STAT3 in mice [12]. These studies suggest that STAT3 may be involved in primordial platelet physiology; however, most evidence is derived from mouse models and cell lines: further validation of its importance in humans is therefore warranted.

This study investigated involvement of STAT3 in platelet activation and platelet numbers in humans. Two independent cohorts were studied. The first cohort concerned patients with STAT3 loss-of-function mutations. STAT3 loss of function is rare but nonetheless observed in humans and results in the hyper IgE syndrome, an immune deficiency disorder associated with recurrent infections, eczema, mucocutaneous candidiasis, and extreme elevations of serum IgE [13,14]. Patients with STAT3 loss of function are deficient in STAT3-dependent cytokines, such as interleukin (IL)-17. It is unknown whether thrombopoiesis and platelet function are affected in humans with mutations in STAT3.

The second cohort concerned healthy human volunteers and investigated the effects of single nucleotide polymorphisms (SNPs) in STAT3 on platelet activation and platelet numbers. These data are important to understand its function on a population level. We demonstrate that both mutations and SNPs in STAT3 do not influence platelet numbers in humans, whereas STAT3 loss-of-function mutations do affect GPVI-mediated platelet activation by CRP. Additionally, we observed that GPVI-mediated platelet activation was largely dependent on secondary stimulation by adenosine di-phosphate (ADP), thereby partially restoring the defect observed in STAT3 loss-of-function patients.

Methods

**Patients selection**

**Cohort 1. Subjects with STAT3 loss-of-function mutations**

Autosomal-dominant cases of hyper IgE syndrome (AD-HIES) are caused by specific mutations that result in nonfunctional STAT3 activity [15]. Most mutations are found at positions that are well known for STAT3 function, such as the Src homology (SH2) domain that enables recruitment and binding of STAT3 to the activated receptor and the DNA-binding domain that enables binding of STAT3 to DNA target sites [14]. The vast majority of AD-HIES cases are due to these heterozygous mutations resulting in absent STAT3 activity; however, several other mutations have been described [13,16]. To examine the effects of STAT3 loss-of-function mutations on platelet numbers, medical records of eight confirmed heterozygous AD-HIES patients were consulted. Additionally, we were able to functionally assess GPVI-mediated platelet activation in 4 of these patients and in 10 control subjects. IL-17 production has been previously tested in peripheral blood mononuclear cells of these patients and the IL-17 deficiency served as a further confirmation of the STAT3 loss of function [17]. Control subjects were healthy individuals who were age and gender matched with AD-HIES patients. No genotyping for specific STAT3 mutations was performed in control subjects because the incidence is exceptionally low and severe medical complaints manifest early in life. The control subjects did not experience any medical complaints during recruitment. Subjects were recruited under a protocol approved by the Institutional Review Board of Radboud University Nijmegen Medical Center. AD-HIES patients are referred to as STAT3 loss-of-function patients.

**Cohort 2. STAT3-related SNPs in healthy subjects**

Several SNPs in STAT3 that are associated with inflammatory diseases were identified from literature [18–20]. In contrast to the STAT3 loss-of-function mutations, the SNPs in STAT3 are associated with inflammatory diseases that are accompanied by increased IL-17 levels. Differentiation of Th-17 cells is dependent on STAT3, which suggests increased STAT3 activity [20]. We determined these SNPs using DNA from the 500 functional genomics cohort and correlated these with GPVI-mediated platelet activation and platelet numbers. This cohort consists of 534 healthy individuals of Caucasian origin and is part of the Human Functional Genomics Project aimed at characterizing variations in immune function [21,22]. More detailed information on the study design and the characteristics of study participants can be found in previous publications [22,23]. Individuals were recruited under a protocol approved by the Institutional Review Board of Radboud University Nijmegen Medical Center.

**Experiments cohort 1**

**Platelet activation and responsiveness assay**

Blood from STAT3 loss-of-function patients during stable disease and healthy subjects was collected in 3.2% sodium citrate vacu-

tainer tubes (Becton Dickinson, Franklin Lakes, New Jersey, USA). Whole blood was centrifuged for 15 min at 156g without break to obtain platelet-rich plasma (PRP). Platelet concentration was adjusted to 300 × 10^6/l by addition of autologous platelet-poor plasma (PPP). PPP was obtained after centrifugation of whole blood at 3800 RPM for 10 min. PRP was rested for 1 h before platelet functions were assessed.

Platelet expression of activation marker P-selectin was measured in PRP at baseline and after incubation for 20 min with different concentrations of platelet agonist cross-linked CRP (kind gift from Prof. Dr. R. Farndale, Cambridge, UK) to stimulate the GPVI surface receptor. Thrombin receptor-activating peptide-6 (TRAP) (Sigma-Aldrich, Saint Louis, Missouri, USA), an agonist for the thrombin receptor proteinase-activated receptor-1, served as a positive control. Samples were incubated with nine concentrations of CRP (range 1.3–320 ng/ml) and two concentrations of TRAP (9.78 and 156 µm) together with antibodies for flow cytometry. The reaction was stopped by addition of 0.2% paraformaldehyde. P-selectin expression was measured with a Becton Dickinson flow cytometer. In order to identify platelets, platelets were gated based on forward and sideward scatter and additional gating was performed based on expression of platelet surface marker CD61 (PC7 labeled anti-CD61, Beckman Coulter, Brea, California, USA). To determine platelet activation, the mean fluorescence intensity (MFI) exceeding that of the matched isotype of P-selectin (PE labeled anti-CD62P, Bio-legend, San Diego, California, USA) was determined.

**Inhibition of ADP pathway with apyrase**

Activation via the GPVI surface receptor results in platelet degrada-
nation of dense granules thereby releasing biologically active substances, most notably ADP. ADP can activate platelets via a secondary pathway. In order to avoid skewing of the responses by platelet activation via this positive feedback loop, additional experiments were performed after preincubation with apyrase, to block the ADP pathway. Apyrase was purchased from Sigma-Aldrich (Saint Louis, Missouri, USA). For experiments, a final concentration 5 U/ml was used. After incubation with apyrase, PRP samples were stimulated with CRP at concentrations 320, 80, and 20 ng/ml in combination with the antibodies for flow cytometry. The same protocol and gating strategies as described above were used.

**Inhibition of transcription during platelet activation**

STAT3, as a transcription factor, regulates DNA transcription and exerts its effects after phosphorylation, dimerization, and translo-
cation to the nucleus [24]. Platelets do not have a nucleus and exclusively contain mitochondrial DNA. Experiments with trans-
scription blocker actinomycin were performed to investigate the role of DNA transcription in this process. Actinomycin was purchased from Sigma-Aldrich (Saint Louis, Missouri, USA) and dissolved in DMSO, stock concentration 6270 µg/ml. PRP was preincubated with actinomycin D in two concentrations (50 and 5 µg) and DMSO control, before samples were stimulated with CRP. The CRP concentration of 40 ng/ml was chosen as it was estimated that platelet responses would be in the steep part of the platelet reactivity curve. The same protocol for stimulation
and similar gating strategies as described above was used for measurement of P-selectin expression.

**Platelet content and plasma markers**

Soluble plasma markers and platelet content of P-selectin, fibrinogen were determined by ELISA. For platelet content, PRP (concentration 300 × 10⁶ platelets/ml) was freeze thawed for three cycles to fragment the platelets. Samples were centrifugated at room temperature for 5 min at 5000 RPM in an ultracentrifuge to spin down large particles. Supernatants were used for ELISA. PPP was used for plasma markers. Soluble P-selectin and soluble fibrinogen were measured using a human P-selectin/CD62P duoset ELISA kit (R&D systems, Europe, Abingdon, UK) and a human fibrinogen ELISA kit (Abcam, Europe, Cambridge, UK), respectively. TPO was measured with a human TPO Quantikine ELISA kit (R&D systems, Europe, Abingdon, UK).

**Experiments cohort 2**

**SNPs in STAT3**

Genotyping of the SNPs was performed using a commercially available SNP chip, Illumina HumanOmniExpressExome-8 v1.0, methods previously reported by Li et al. [23]. In short, genotype calling was performed using Optical 0.7.0 [25]. Call rates less than ≤0.99 were excluded from the dataset, as were samples with a Hardy–Weinberg equilibrium ≤0.0001, call rate ≤0.99, and minor allele frequencies (MAF) ≤0.001. In total, 483 samples were included for further imputation, as described previously. Data were extracted for the following SNPs: rs744166, rs3816769, and rs4796793. Presence of the SNP was related to platelet activation in response to CRP and to platelet numbers.

**Platelet activation and responsiveness assay**

For assessment of platelet activation and responsiveness, platelet P-selectin expression was measured in whole blood at baseline and after incubation for 20 min with seven different concentrations of platelet agonists CRP, together with an antibody mix for flow cytometry. The same protocol and gating strategies as described above were used for measurement of P-selectin expression. The area under the curve (AUC) of the P-selectin expression was measured in whole blood at baseline and after incubation for 20 min with seven different concentrations of platelet agonists CRP, together with an antibody mix for flow cytometry. The same protocol and gating strategies as described above were used for measurement of P-selectin expression. The area under the curve (AUC) of the P-selectin expression.
Inhibition of the ADP pathway further attenuates platelet responsiveness in STAT3 loss-of-function patients

GPVI-mediated platelet activation results in platelet degranulation, thereby releasing biologically active substances, in particular ADP from dense granules [26]. In order to investigate dependency of the GPVI-mediated platelet activation pathway on secondary ADP release, we incubated samples with apyrase to block this pathway. Stimulation of the GPVI receptor by different concentrations of CRP after incubation of samples with apyrase resulted in considerably lower P-selectin expression in both groups. Inhibition of the ADP pathway seems to have a more profound effect in STAT3 loss-of-function patients than in healthy subjects, as the relative increase from baseline to the highest CRP concentration was 5.7-fold in STAT3 loss-of-function patients compared to 11.4-fold in control subjects (Figure 1D).

No differences in platelet content and soluble markers were found in STAT3 loss-of-function patients

Previous experiments suggest an intrinsic platelet defect in patients with STAT3 loss-of-function mutations. In addition, inhibition of the ADP pathway had a relatively higher impact on GPVI-mediated platelet activation in STAT3 loss-of-function patients. To examine whether these observations were a result of alterations in granule content, we measured P-selectin and fibrinogen in platelet lysates. No differences were seen in platelet content for P-selectin and fibrinogen (327.0 ng/ml [IQR 153.9–523.5] in patients vs. 261.1 ng/ml [IQR 204.3–325.5] in control subjects, p-value 0.84 and 2420 µg/ml [IQR 1786–3813] in patients, and 2092 µg/ml [IQR 1038–2938] in control subjects, p-value 0.52, respectively). This suggests that previous observations are more likely due to lower platelet granule release in response to stimulation than alterations in granule content.

Lastly, P-selectin and fibrinogen in plasma was determined as a measure for platelet granules release. Interestingly, no significant differences were found in soluble plasma P-selectin and fibrinogen between patients and control subjects (median 41.7 ng/ml [IQR 27.0–47.3] vs. 27.9 ng/ml [21.9–44.2], p-value

Specification of the STAT3 loss-of-function mutations. DNA: Deoxyribonucleic acid; SH2: Src Homology 2. Patients indicated with an asterisk (*) were functionally assessed. (1): one of the 2 patients was functionally assessed.
SNPs in STAT3 do not correlate with GPVI-mediated platelet activation in healthy volunteers

To investigate the involvement of STAT3 on platelet activation on a population level, several SNPs in STAT3 that are associated with inflammatory diseases were investigated. The three SNPs, rs744166, rs3816769, and rs4796793, were determined in the second cohort, concerning healthy volunteers. These SNPs are known from literature to be functional and are likely to influence STAT3 activity in relation to several diseases, such as Crohn’s disease, ulcerative colitis, and autoimmune thyroid disease [18–20]. The MAF of rs744166, rs3816769, and rs4796793 were \( C = 0.439/964, C = 0.254/964, \) and \( C = 0.378/964, \) respectively. The MAFs were similar to the MAFs reported in the NCBI database (http://www.ncbi.nlm.nih.gov/SNP), except for rs3816769 with a MAF of \( C = 382/1912 \) in the NCBI database. Linear regression analysis was performed for SNP genotype and platelet activation in response to GPVI stimulation (AUC). No significant correlations could be detected for rs744166, rs3816769, and rs4796793 with GPVI-mediated platelet activation \( (p > 0.05) \). The SNP characteristics and the relation between the SNPs and GPVI-mediated platelet activation are shown in Figure 2. In contrast to previous observations, SNPs in STAT3 do not seem to affect GPVI-mediated platelet activation.

Platelet numbers are not influenced by STAT3 mutations and STAT3 SNPs

Lastly, we studied platelet production. Platelet production is primarily regulated by TPO concentrations in blood and it has recently been suggested that hepatic TPO production is dependent on signaling via STAT3 [12]. Platelet numbers retrieved from medical records of eight confirmed STAT3 loss-of-function patients were mostly within the normal range (Table III). Interestingly, thrombocytosis was observed in two patients during an acute infection. Thrombocytopenia was not observed in STAT3 loss-of-function patients. In addition, plasma TPO levels were determined in the 4 functionally assessed STAT3 loss-of-function patients and the 10 healthy subjects. Although most values were below the detection limit of 15.6 pg/ml, two STAT3 loss-of-function patients had detectable TPO levels (24.0 and 79.7 pg/ml) (Figure 3A). Several studies suggest that IL-6 stimulates thrombopoiesis [27,28]. Therefore, we determined IL-6 levels in plasma. A trend for higher IL-6 was observed in STAT3 loss-of-function patients (Figure 3B).

Also the effects of the SNPs in STAT3 were examined. Consistently with the observation in the STAT3 loss-of-function patients, no significant influence of the SNPs on platelet numbers was observed in 334 healthy subjects (Table III). Importantly, both thrombocytopenia and thrombocytosis were rarely observed.

Discussion

The present study investigated the involvement of STAT3 in GPVI-mediated platelet activation and platelet numbers in humans. Our findings indicate that GPVI-mediated platelet activation is affected by STAT3 loss-of-function mutations confirming its involvement in platelet function in humans. In contrast, neither clinically relevant STAT3 loss-of-function mutations nor SNPs in STAT3 affected platelet numbers in humans.

Further experiments were performed to increase our understanding of its function. GPVI-mediated platelet activation was shown to be largely dependent on secondary stimulation by platelet ADP release, both in patients and in healthy subjects. Blockade of this mechanism strongly attenuated platelet responses, particularly in STAT3 loss-of-function patients. These observations were independent of gene transcription, as previously reported [9]. Although STAT3 is commonly known as a transcription factor, its involvement in platelet activation appears to be non-transcriptional and few non-transcriptional properties of STAT3 have been previously described [29,30]. SNPs in STAT3 did not directly affect GPVI-mediated platelet activation in a healthy population. In some inflammatory diseases, the effects of SNPs in STAT3 on platelet activation may become apparent; however, in healthy individuals, robust mechanisms seem to balance inflammation and hemostasis.

Interestingly, P-selectin levels in plasma were not different between STAT3 loss-of-function patients and control subjects, whereas platelet degranulation was decreased in patients. Another source for soluble P-selectin is the vascular endothelium [31]. Both vascular abnormalities and endothelial dysfunction are common in hyper IgE syndrome and may explain this observation [32].

With the lack of an effect on platelet numbers, we report an opposite effect compared to a previous study that suggests an important role for STAT3 in the hepatocytic production of TPO, the most important regulator of platelet formation by megakaryocytes [12]. In addition to a mouse model, it was shown that desialylated platelets are taken up by a human HepG2 cells and these cells subsequently
produce TPO in a Janus kinase-2 (JAK2)/STAT3-dependent manner [12]. In contrast, we did not find a decrease in platelet numbers in patients with defective STAT3 signaling; moreover, thrombocytosis was observed in STAT3 loss-of-function patients during acute infections. TPO levels were detectable in plasma in two patients, whereas these were low or undetectable in control subjects. A direct comparison between groups is limited by the fact that TPO was undetectable in most subjects and these results should be interpreted with caution. A trend was seen for increased IL-6 in patients and this may also appear in inflammatory diseases. Our findings suggest that in vivo other mechanisms also regulate platelet production in humans.

The observation that STAT3 is involved in GPVI-mediated platelet activation further validates that the mechanism reported by Zhou and colleagues may be functional and relevant in humans too [9]. Involvement of STAT3 in platelet activation may provide a relevant link between inflammation and hemostasis. Increased activation of the STAT3 signaling pathway has been described in cancer and many inflammatory diseases, including cardiovascular diseases [4–8, 33]. Cardiovascular disease is the leading cause of death worldwide and interestingly, risk for cardiovascular diseases is strongly increased in many inflammatory diseases [34]. To examine whether GPVI-mediated platelet activation was affected by SNPs in STAT3, we studied a cohort of healthy human volunteers; however, no relation was observed. The role of STAT3 activation in inflammatory diseases and its consequences for platelet activation needs further exploration. Especially since it is unknown if the SNPs in STAT3 affect STAT3 function in healthy subjects, or whether aberrant STAT3 function becomes apparent in inflammatory diseases.

Blockade of STAT3 is currently being explored as a new therapy for cancer [35, 36]. Several STAT3 inhibitors have recently proceeded into clinical trials and also drugs that block JAK2, such as Ruxolitinib [35, 37, 38]. It is important that involvement of STAT3 in platelet activation is recognized. Bleeding complications may occur, especially in patients who are concurrently treated with platelet inhibitors that target other pathways such as Ticagrelor and Clopidogrel, targets of the ADP receptor, P2Y12. GPVI-mediated platelet activation is highly dependent on secondary activation via ADP and suppression of both pathways may have important consequences in terms of bleeding [39–41].

The relevance of the functional impairment in patients with AD-HIES seems to be limited due to the positive feedback loop by ADP, which partially restores platelet responses. Although severe bleeding complications are reported, they mostly coincide with opportunistic infections in AD-HIES patients who often have bronchiectasis, both features known to provoke pulmonary hemorrhages [42, 43]. Interestingly, in one AD-HIES patient, a spontaneous bleeding was recorded that could not be explained from a clinical perspective. The bleeding occurred in the iliohypogastric muscle and was not preceded by any kind of trauma. Examination of the medical history of the other patients did not reveal any unexplained spontaneous bleedings.

Our study has a few limitations. The first limitation is that we were unable to relate platelet responses directly to STAT3 function and different STAT3 isoforms. STAT3 has several isoforms that mostly result from alternative mRNA splicing. These isoforms can have distinct functions; STAT3β, for example, lacks the Ser727 phosphorylation site and is thought to be a negative regulator [44]. The exact mechanisms by which STAT3 mutations cause STAT3 loss-of-function are still largely unknown [14]. It would have been of great interest to directly relate STAT3 isoforms and STAT3 activity to GPVI-mediated platelet responses. Also the question whether there is a compensatory increase in other STATs needs further investigation, as STATs can both form homodimers and heterodimers with different functions [44]. The second limitation is the limited sample size of STAT3 loss-of-function patients (AD-HIES patients). This makes our findings less robust. AD-HIES is a very rare disease with an estimated prevalence of 1:100 000 [14, 45]. It has to be noted that the effects observed were consistent in patients and in different

Platelet numbers from STAT3 loss-of-function patients, platelets × 10^9/l, and platelet numbers from the SNP cohort, median platelet numbers × 10^9/l (range). Patients indicated with an asterisk (*) were functionally assessed. ♀: Female; ♂: male; SNP: single nucleotide polymorphism.

Figure 3. TPO and IL-6 levels in plasma. (A) Plasma TPO levels in STAT3 loss-of-function patients and control subjects. (B) Plasma IL-6 expression in STAT3 loss-of-function patients and control subjects (IL-6: Interleukin-6; TPO: thrombopoietin).
concentrations of CRP. Lastly, STAT3 loss-of-function patients are treated with prophylactic antimicrobial therapy and we were unable to correct for those differences in the healthy subjects. Therefore, we cannot completely exclude a potential effect of medication on our findings.

In conclusion, our findings indicate that STAT3 is involved in GPVI-mediated platelet activation by CRP in humans. Additionally, GPVI-mediated platelet activation was shown to be largely dependent on secondary stimulation by ADP. In contrast, neither clinically relevant STAT3 loss-of-function mutations nor SNPs affecting STAT3 activity influence platelet numbers in humans. These data improve our understanding on the interaction between inflammation and hemostasis and suggest that STAT3 modulation may affect both inflammation and hemostasis and their interaction in humans.
