Sex-differences

ABSTRACT

Emotional eating (EE), or eating in response to negative emotions, was earlier shown to be associated with difficulty in identifying emotions (alexithymia). To improve our understanding of possible causes of alexithymia and EE, we assessed possible associations with duration of breastfeeding in infancy. The aim of the present study was to examine in a prospective, longitudinal study whether duration of breastfeeding is associated with EE in adolescence, through its effect on alexithymia difficulty identifying emotions, and whether this mediation effect is contingent on gender. Our hypothesis was that longer duration of breastfeeding would be associated with lower EE in adolescence through its effect on lower alexithymia difficulty identifying feelings in boys but not in girls (Moderated mediation). The sample included 129 children and their families (67 boys and 62 girls). Duration of breastfeeding was reported by the mother when the infant was 15 months old. Alexithymia difficulty identifying feelings (Toronto Alexithymia Scale) and EE (Dutch Eating Behavior Questionnaire) were reported by the child at 12 years of age. EE was also reported by the child at 16 years of age. Moderated mediation was significant for EE at 12 years, and borderline significant for EE at 16 years. As hypothesized, for boys but not for girls, longer duration of breastfeeding was related to less difficulties in identifying feelings, resulting in lower degrees of EE in adolescence. It is concluded that breastfeeding in infancy may protect boys against EE through its positive association with better ability to identify feelings.

1. Introduction

Emotional eating (EE), defined as eating in response to negative emotions (Van Strien, Donker, & Ouwens, 2016), is associated with prospective weight gain (Koenders & Van Strien, 2011; Van Strien, Herman, & Verheijden, 2012), binge eating in adult (clinical) samples (Klump et al., 2014; Van Strien, Engels, Van Leeuwe, & Snoek, 2005), and acts as a mediator between depression and weight gain (Van Strien, Kontinen, Homberg, Engels, & Winkens, 2016; Vittengl, 2018). EE is an a-typical stress response. The typical stress response is *not* eating, because the physiological stress reactions mimic the internal sensations associated with feeding induced satiety (Gold & Chrousos, 2002). It has been postulated that the a-typical stress response of EE develops early in life (Wardle, 1990), as a possible outcome of parental feeding practices (Carper, Fisher, & Birch, 2000; Van Stien and Bazelier, 2007; Van Strien, Van Niekerk, & Ouwens, 2009) and more general parenting practices where there was insufficient regard for the child's needs

(Bruch, 1973; Snoek, Engels, Janssens, & Van Strien, 2007; Escobar et al., 2014; Zhu, Luo, Cai, Li & Liu, 2014). If parental responses to the child's needs are continuously inappropriate, be it neglectful, indiscriminately permissive or over-controlling, the child may develop i) poor satiety awareness (poor awareness of physiological symptoms associated with hunger and satiety) and ii) poor emotional awareness (poor awareness of emotions, resulting in difficulty identifying and describing emotions, also referred to as alexithymia¹) (Garner, 1991). Poor satiety awareness and alexithymia were indeed shown to be associated with higher EE (Larsen, van Strien, Eisinga, & Engels, 2006; Van Strien et al., 2005; Van Strien & Ouwens, 2007). The present study focusses on the feeding practice of breastfeeding. As will be elaborated below, there is ample evidence that breastfeeding is associated with satiety awareness, and that breastfeeding may be associated with EE through its impact on satiety awareness. In contrast, there is only circumstantial evidence that breastfeeding may also be associated with alexithymia. Therefore, the present study aims to examine whether

¹ Alexithymia comes from Greek: ἀ- (a-, 'not') + λέξις (léxos, 'word') + θῦμός (thýmós, 'heart' or 'emotions'), and literally means "no word for emotions".

duration of breastfeeding is associated with EE in adolescence, through its effect on alexithymia.

1.1. Breastfeeding and satiety awareness

There is ample evidence that duration of breastfeeding is associated with satiety awareness. For example, when compared to formula fed infants, breastfed infants are rated by their mothers to have a better satiety awareness and appetite regulation (Brown & Lee, 2012; Disantis, Collins, Fisher, & Davey, 2011; Reyes et al., 2014). Several biological constituents present in breast milk, but absent in infant formula, could be responsible for the better satiety awareness of breastfed infants. For example, breast milk contains many hormones, including leptin. Leptin, also referred to as the satiety hormone, helps to regulate the energy balance by inhibiting hunger. A decreased sensitivity to leptin results in an inability to detect satiety, and has been related to obesity and emotional eating (Michels, Sioen, Ruige, & De Henauw, 2017; Schwartz, Woods, Porte, Seeley, & Baskin, 2000). Furthermore, breast milk changes in energy density and fat content during the day (Nommsen, Lovelady, Heinig, Lönnerdal, & Dewey, 1991). Breastfed infants learn to respond to this variation and to match their own intake to their needs (Brown & Lee, 2012).

1.2. Breastfeeding and alexithymia

In contrast to ample evidence on the positive association of breastfeeding with a better awareness of satiety, only circumstantial evidence exists on the possible association of breastfeeding with awareness of emotions (alexithymia). A link between breastfeeding and alexithymia could be hypothesized on the following grounds.

First, breastfeeding could be a protective factor for later alexithymia and emotional eating, because breastfeeding is regarded as a more responsive style of feeding (Shloim, Shafiq, Blundell-Birtill, & Hetherington, 2018; Shloim, Vereijken, Blundell, & Hetherington, 2017). When breastfeeding, the mother has to rely on the feeding signals of the infant (e.g. turning head away), rather than on external cues such as the quantity of milk left in the bottle (Woo & Martin, 2015). Next to increased responsiveness during the lactation period, breastfeeding was shown to set the stage for less controlling and more responsive parental feeding and parenting practices later in childhood (Brown & Arnott, 2014; Jansen, Mallan, Byrne, Diet, Daniels, & Nicholson, 2016; Taveras, Scanlon, Bearch, Rifas-Shiman, Rich-Édwards, & Gillman, 2004; Ventura, 2017; Weaver, Schofield, & Papp, 2018). For example, a recent study using data from the large NICHD study found that longer breastfeeding duration predicted increases in observed maternal sensitivity up to child age 11 years (Weaver et al., 2018). In turn, more sensitive and cooperative parenting is associated with lower degrees of the alexithymia aspects difficulties identifying emotions and difficulties describing emotions (see the meta-analysis of Thorberg, Young, Sullivan, & Lyvers, 2011).

Second, unlike formula milk, breast milk contains small amounts of hormones, (Uvnas-Moberg, 1998). Accumulating evidence suggests that hormones from the mother ingested through milk, affect the offspring's own hormonal concentrations and developing brain (Hinde et al., 2014). Breast milk also includes the hormone oxytocin (OT). OT has been shown to facilitate socio-emotional abilities, including sensitivity and attunement to emotional expressions of others. This sensitivity and attunement is impaired in people with high degrees of alexithymia (Grynberg et al., 2012), possibly because awareness of others' emotions is related to awareness of one's own emotions. It can thus be hypothesized that increased exposure to oxytocin, through longer breastfeeding duration, predicts higher sensitivity to emotional expressions of others and lower degrees of alexithymia (Luminet, Grynberg, Ruzette, & Mikolajczak, 2011). Research supports this hypothetical mechanism. For example, the social impairment of men with high degrees of alexithymia could be remedied by intranasal

Fig. 1. Conceptual diagram of moderated mediation: moderation of sex (W) on the mediation effect of alexithymia identifying feelings (M) between duration of breastfeeding (X) and EE (Y).

administration of oxytocin (Luminet et al., 2011). Moreover, Krol, Rajhans, Missina, and Grossmann (2015a) found that exclusive breastfeeding duration was positively associated with attention to emotional bodily and facial expressions from others. The hypothesis that oxytocin is the underlying mechanism of this association was supported in a subsequent study (Krol, Monakhov, San Lai, Ebstein, & Grossmann, 2015b). In this study, the effect of exclusive breastfeeding on attention to emotional expressions was shown to be most pronounced in infants with a genotype that was associated with a decreased availability of oxytocin (Krol et al., 2015b), perhaps because the small quantities of oxytocin in breast milk act “as a transcriptional promoter of the oxytocin gene” (Shafai, Mustafa, Mulari, & Curtis, 2017, p. 80). To our knowledge, however, the hypothesis that shorter duration of breastfeeding is associated with higher degrees of alexithymia, and subsequently with more EE in adolescence, has not been investigated.

1.3. Differential sex effects

The mediation effect of alexithymia in the association between breastfeeding duration and EE may be moderated by sex (see Fig. 1 for the model of moderated mediation). Breastfeeding may particularly protect boys against high degrees of alexithymia. Evidence suggests that effects of parenting are sex-specific, as particularly boys seem to be protected against emotional disorders by responsive parenting (Browne, Oduyungbo, Thabane, Byrne, & Smart, 2010). Moreover, the effects of oxytocin on social sensitivity and awareness of emotions have also been shown to be sex specific, with no, or even opposite, effects during social interaction in women. That is, whereas social interactions showed improvement in men, the interactions deteriorated in women after oxytocin administration (e.g. Rilling et al., 2014). Combined with the lower capacity for empathy (Christov-Moore et al., 2014) and the higher prevalence of alexithymia in men (Levant, Hall, Williams, & Hasan, 2009), we hypothesized that the mediation effect only holds true for boys.

1.4. Present study

Taken together, breastfeeding duration may be associated with lower alexithymia because: 1) breastfeeding is associated with a more responsive style of parenting, which, in turn, is associated with lower degrees of alexithymia, and 2) the oxytocin present in breast milk may contribute to a better ability to identify emotions of others, which may be related to a better ability to also identify one's own emotions. Together with evidence that alexithymia is positively associated with EE (e.g. Larsen et al., 2006), we expected alexithymia to be a mediator between breastfeeding duration and EE. A longer duration of breastfeeding is hypothesized to be associated with less emotional eating through a better ability to identify feelings, compared to a shorter duration of breastfeeding. We focused our hypothesis on the alexithymia aspect identifying feelings, as we suggest that breastfeeding has an impact on this specific alexithymia aspect and not the alexithymia aspect describing feelings. We further expected this hypothesis to be

only true for boys, not girls.

We tested our hypothesis in a prospective longitudinal study. Duration of breastfeeding was reported by the mother when the child was 15 months old. Alexithymia and EE were reported by the child at the age of 12 years. EE was also assessed at 16 years by child self-report. This enabled us to improve our test of the causal chain, because not only the predictor but also the mediator preceded emotional eating in real time. In order to examine whether the moderated mediation model is specific for EE, we also assessed the effects of breastfeeding through alexithymia on external eating (eating in response to external food cues such as smell and sight of food). External eating was reported by the child at 12 years and 16 years of age.

2. Method

2.1. Participants

The research questions of this study were addressed using data from the Nijmegen Longitudinal Study on Infant and Child Development. This study started in 1998 with a community sample of 129 healthy 15-month-old children (52% boys) and their primary caregivers. For the Nijmegen Longitudinal Study on Infant and Child Development, the following IRB approvals had been obtained: ECSW20213-1811-157 and ECG2013-1308-123/feature: COM/MB/13U.016212. The families were recruited on the basis of records from local health-care centers in the city of Nijmegen (The Netherlands). Families with a 15-month-old baby were sent an invitation to participate in the study that aimed to gain more insight into children's development in the first years of life. If they met the two eligibility criteria (i.e., sufficient fluency in Dutch and child without serious health problems) and were interested in participation, they could return a response card. Of the 639 families approached, 174 replied and 129 families were randomly selected for the study (129 families was the maximum attainable given the time and resources available for the project at that moment). As indicated by the distribution of parental and child measures at 15 months, the initial sample was representative of the Dutch population of families with young children (Van Bakel & Riksen-Walraven, 2002a, 2002b). In 126 families, the mother was the primary caregiver and in the remainder of the families this was the father. The primary caregivers were between 22 and 47 years of age at the time of the recruitment.

Of the original sample of 129 children, 111 children participated at age 12 ($M_{\text{age}} = 12.38$ years, $SD = 0.28$; 52% boys) and 101 children at age 16 ($M_{\text{age}} = 16.25$ years, $SD = 0.30$; 50% boys). See Fig. 2 for an overview of the recruitment process and drop-out of the study. To determine whether there was selective drop-out or not, the participating families in the 12- and 16-year assessment were compared to the families that did not take part on the study variables included in the present study (i.e., duration of breastfeeding, and paternal and maternal level of education). Independent *t*-tests revealed no significant differences. Of the children who participated, 104 children had complete data at age 12 (54 boys and 50 girls) and 91 children at age 16 (44 boys and 47 girls).

2.2. Procedure

During a home visit at 15 months, the primary caregiver was interviewed about duration of breastfeeding. At 12 years of age, data was collected during a home visit after the parents had given informed active consent and the children had given verbal assent. During the home visit, children completed a questionnaire to assess alexithymia, EE and external eating behaviors. At 16 years of age, schools were asked to give informed permission for the project after the parents and the children had given active informed permission to approach the schools. Active consent was given by the school. Children completed questionnaires on EE and external eating behaviors during a classroom session.

2.3. Measures

2.3.1. Duration of breastfeeding

Breastfeeding information was collected at 15 months of age regarding the duration of breastfeeding in months. Mothers were asked “Did you breastfeed your baby?”. If they said “no” this was recorded as “never breastfed.” If they said “yes” they were asked “At what child age did you stop breastfeeding?”. Maternal recall is found to be a valid and reliable estimate of breastfeeding initiation and duration, especially when the duration of breastfeeding is recalled after a short period (Li, Scanlon, & Serdula, 2008). Duration of any breastfeeding was defined as the age at which breastfeeding stopped and was expressed as a continuous variable (in whole and half months).

2.3.2. Alexithymia

At 12 years, alexithymia “difficulty identifying feelings” and “difficulty describing feelings” were assessed, respectively, with 7 (e.g. “I have feelings that I can't quite identify”; Cronbach's alpha 0.71), and 5 (e.g. “It is difficult for me to find the right words for my feelings”; Cronbach's alpha 0.72) items of the Toronto Alexithymia Scale-20 (TAS-20; Bagby, Parker, & Taylor, 1994; Kooiman, Spinhoven, & Trijsburg, 2002; adjusted for children by Rieffe, Oosterveld, & Terwogt, 2006). The TAS-20 was chosen for the present study, as this questionnaire is designed to detect individuals who are alexithymic, and because the TAS-20 outperforms the LEAS (Levels of Emotional Awareness Scale; Lane, Quinlan, Schwartz, Walker, & Zeitlin, 1990) when it comes to the assessment of the alexithymia aspect difficulty identifying feelings. Items were rated along a 3-point scale ranging from “disagree” (1) to “agree” (3). Scores for the scales were obtained by computing the mean of the items, with higher scores indicating more difficulty in identifying or describing emotions.

2.3.3. Emotional and external eating

At 12 years, EE and external eating were assessed, respectively, with 7 items (“If things go wrong do you get a desire for food?”; Cronbach's alpha 0.73), and 6 items (“Do you feel like eating whenever you see or smell good food?”; Cronbach's alpha .071) of the Dutch Eating Behavior Questionnaire for Children (DEBQ-C). The DEBQ-C is an age-adapted 20-item version of the Dutch Eating Behavior Questionnaire (Van Strien, 2015), which is suitable for 7–12 year old children (Van Strien & Oosterveld, 2008). The items had a three-point response format: (1) no – (5) yes.

At 16 years, EE and external eating were assessed with 6 (Cronbach's alpha 0.94), respectively 7 items (Cronbach's alpha 0.84) of the brief 20-item version of the adult DEBQ (see also, Van Strien, Donker, et al., 2016; Paans et al., 2018). The items had a five-point response format: (1) never – (5) always. For both versions of the DEBQ, scale scores were obtained by computing the mean of the items. Higher scores reflect, respectively, more emotional and external eating.

2.3.4. Parental level of education

Paternal and maternal level of education was rated on a 7-point scale ranging from low (elementary school) to high (college degree or higher).

2.4. Statistical analyses

All analyses were carried out using SPSS version 23.0 (IBM Corporation, 2015). Moderated mediation (Fig. 1) was assessed with the PROCESS macro of SPSS version 23.0, developed by Hayes (2013, PROCESS macro, model 7). Moderated mediation in Model 7 is analysed with two regression equations (see Fig. 3, for the statistical diagram). In analysis 1) X, W, and the XW interaction are regressed on the mediator (M); In analysis 2) M and X are regressed on the dependent variable (Y). All variables were centred before computing interaction terms (e.g. sex X duration of breastfeeding, see Fig. 3). Significance of

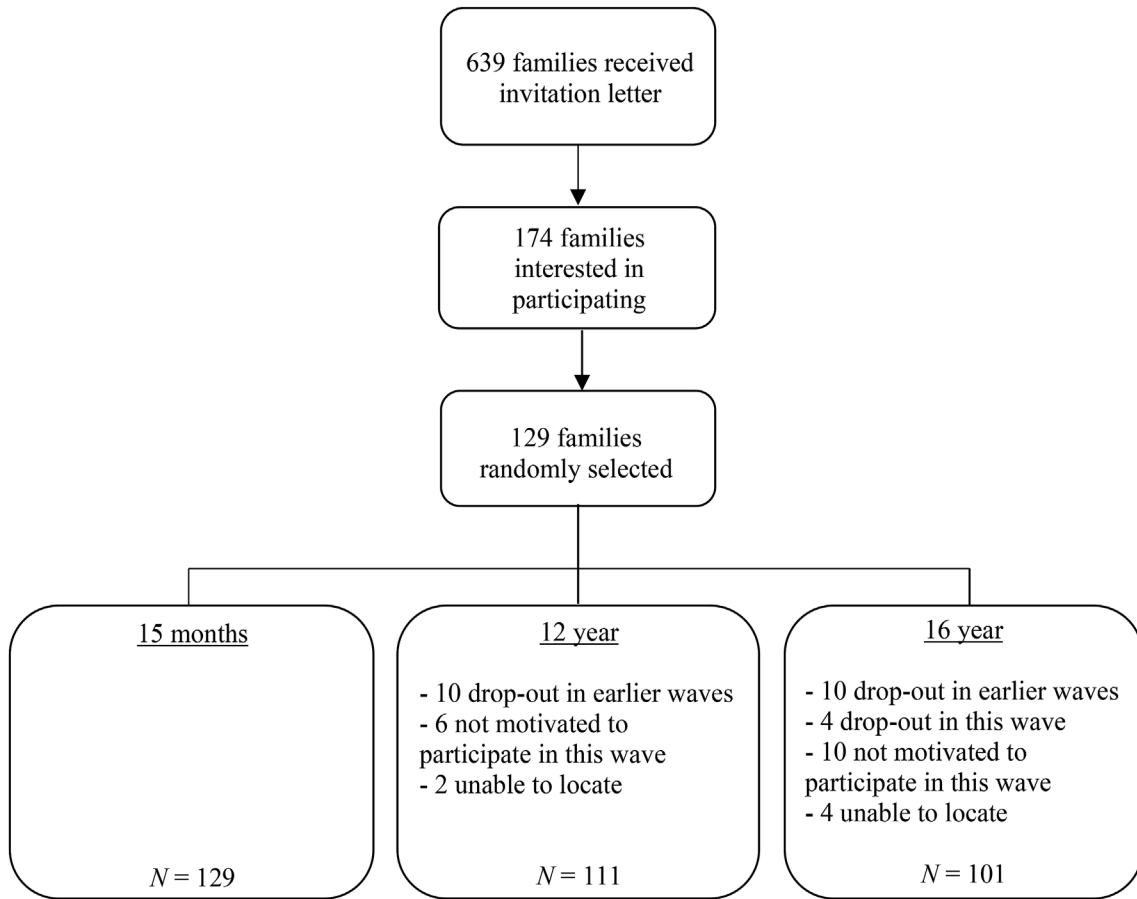

Fig. 2. Flow chart of the sample of the Nijmegen Longitudinal Study on Infant and Child Development.

moderated mediation was tested with Hayes' index of moderated mediation (Hayes, 2015). A test was deemed significant if the 95% bootstrap bias corrected confidence interval (CI) did not include zero. Bootstrapping with 5000 samples was used because “bootstrapping does not impose the assumption of normality of the sampling distribution” (Preacher & Hayes, 2008, p. 880). In case the index of moderated mediation of our main research question was *not* significant at 95% bias corrected CI, we proceeded our analyses with a test of

mediation only (PROCESS macro, model 4, not shown).

To assess the specificity of our moderated mediation model for the mediator alexithymia identifying feelings, we also tested the model for alexithymia describing emotions. In order to examine whether the above moderated mediation model is specific for EE, we assessed in an additional analysis the effects of breastfeeding duration through alexithymia on external eating.

Given that breastfeeding may be positively associated with parental

level of education (Thulier & Mercer, 2009), it was included as a covariate in the models. Because paternal and maternal level of education were highly interrelated ($r = 0.69$), the mean was calculated and included in the analyses. Because of high interrelations between EE and external eating ($r > 0.55$) we controlled in an additional analysis also for external eating (in the model with EE as dependent variable), and for EE in the additional model with external eating as dependent variable.

3. Results

3.1. Preliminary analyses

Table 1 shows means, standard deviations, and inter-correlations between the study variables for boys and girls separately. In both sexes, duration of breastfeeding was not significantly associated with alexithymia difficulty identifying and difficulty describing feelings, and also not with EE at 12 years or at 16 years of age. Furthermore, alexithymia difficulty identifying feelings was significantly associated with EE at 12 years for both boys and girls, and with EE at 16 years for boys only. Alexithymia difficulty identifying feelings and difficulty describing feelings were highly interrelated, and the same held true for EE and external eating at 12 years and 16 years. Only in girls, parental educational level was significantly associated with EE at 12 years and at 16 years of age.

3.2. Moderated mediation with EE at age 12 years as outcome variable

Fig. 4 shows the results of the moderated mediation analysis (PROCESS, model 7) with sex as moderator variable (W) and alexithymia identifying feelings at 12 years as mediator (M) in the link between breastfeeding duration (X) and EE at 12 years of age (Y). In the model with no confounders, the index of moderated mediation was significant ($B = 0.035$ ($SE = 0.017$), 95% BootCI [0.0050, 0.0754]). Inspection of the conditional indirect effects revealed that there was a significant negative mediation effect of alexithymia difficulty identifying feelings for the boys ($B = -0.017$ ($SE = 0.01$), 95% BootCI [–0.037, –0.0025]), whereas there was no significant mediation effect of alexithymia difficulty identifying feelings for the girls ($B = 0.018$ ($SE = 0.014$), 95% BootCI [–0.0080, 0.0487]). The index of moderated mediation remained significant when controlling for the possible confounder parental educational level ($B = 0.036$, ($SE = 0.018$), 95% BootCI [0.0057, 0.0743]), and the same held true when we additionally controlled for external eating ($B = 0.0253$ ($SE = 0.0129$), 95% BootCI [0.0045, 0.0556]). In all additional models, there was a 95% Boot CI significant negative mediation effect for

alexithymia difficulty identifying feelings between duration of breastfeeding and EE in boys (see Fig. 5 for an illustration of the mediation effect in the boys).

3.2.1. Specificity of the model at 12 years for EE

In a subsequent analysis, it was tested whether the model is specific for EE by testing the model with external eating instead of EE as dependent variable (Y). Though the index of moderated mediation was significant in the model with no confounders ($B = 0.0235$ ($SE = 0.0160$), 95% BootCI [0.0025, 0.0665]), the index of moderated mediation was no longer significant in the full model when we controlled for parental educational level and EE ($B = 0.0011$ ($SE = 0.0077$), 95% BootCI [–0.0114, 0.0214]). This indicates that the model is specific for EE, because the index of moderated mediation remained significant in the initial model with EE as dependent variable, when additionally controlling for parental educational level and external eating in the full model.

3.2.2. Specificity of the model at 12 years for alexithymia identifying feelings

To test the specificity of the model for alexithymia identifying feelings, the initial model with EE as dependent variable (Y) was also tested with the alexithymia scale difficulty describing feelings as mediator (M). The index of moderated mediation was not significant ($B = -0.0025$ ($SE = 0.0100$), 95% BootCI [–0.0255, 0.0150]). This indicates that the model is indeed specific for alexithymia difficulty identifying feelings.

3.3. Moderated mediation with EE at age 16 years as outcome variable

A limitation of the previous moderated mediation analysis, is that the mediator and outcome had been simultaneously measured with one questionnaire at 12 years of age. In order to test the robustness of this causal chain as a causal chain in real time, we proceeded with re-conducting our analyses using the DEBQ scales on EE and external eating at 16 years of age ($n = 91$). The index of moderated mediation of the initial model (without confounders) was significant ($B = 0.0242$ (Boot $SE = 0.0156$), 95% BootCI [–0.0002; 0.0625]). The index of moderated mediation analysis remained significant when we controlled for parental educational level ($B = 0.0254$ (Boot $SE = 0.0158$), 95% BootCI [0.0007; 0.0651]). When we additionally controlled for external eating, the index of moderated mediation became borderline significant (90% Boot CI): $B = 0.0207$ (Boot $SE = 0.0150$), 90% BootCI [0.0015, 0.0536]. Inspection of the conditional indirect effects in the latter (full) model revealed that there was a 90% Boot CI borderline significant negative mediation effect of difficulty identifying feelings for the boys

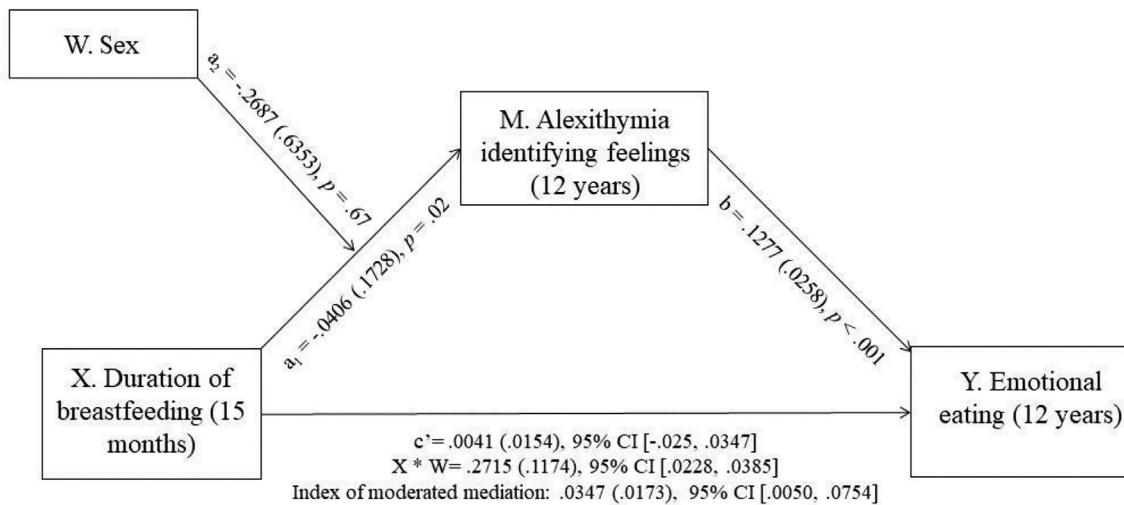

Fig. 4. Moderation of sex (W) on the mediation effect of alexithymia identifying feelings (M) between duration of breastfeeding (X) and EE (Y). There is a significant interaction effect of sex. Only in the boys a longer duration of breastfeeding is associated with a subsequent lower degree of alexithymia identifying feelings, resulting in lower EE (see Fig. 5).

Fig. 5. Mediation effect of alexithymia identifying feelings (M) between duration of breastfeeding (X) and emotional eating (Y) in the boys. The indirect effect of X on Y is significant ($B = -0.0167$) (Boot SE = 0.0094), 95% BootCI [$-0.0405, -0.0026$].

($B = -0.0103$ (SE = 0.0076), 90% BootCI [$-0.0267, -0.0011$]), whereas there was no significant or borderline significant mediation effect of difficulty identifying feelings for the girls ($B = 0.0104$ (SE = 0.0110), 90% BootCI [$-0.0016, 0.0349$]).

3.3.1. Specificity of the model at age 16 years for EE

In the model with external eating as dependent variable (Y), the index of moderated mediation of the initial model (without confounders) was not significant, also not at 90% (BootCI: $B = 0.0056$ (Boot SE = 0.0085), 90% BootCI [$-0.0051, 0.0232$]). This remained so when controlling for parental educational level and EE (not shown).

3.3.2. Specificity of the model at age 16 years for alexithymia identifying feelings

When testing the model with EE as dependent variable (Y) and alexithymia difficulty describing feelings as mediator (M), the index of moderated mediation was also not significant at 95% BootCI or 90% BootCI (not shown).

4. Discussion

In this prospective study, we tested the hypothesis that breastfeeding duration is associated with subsequent emotional eating (EE) in adolescence, through its impact on alexithymia difficulty identifying feelings. We expected this hypothesis to be only true for boys, not girls. We thus expected that in the boys, a longer duration of breastfeeding would result in a lower degree of alexithymia identifying feelings,

which, in turn, would result in a lower degree of EE. This hypothesis was significantly supported when investigating EE at 12 years, and borderline significantly supported when investigating EE at 16 years.

We found that breastfeeding duration was not related to alexithymia and subsequent EE in girls, which is consistent with some circumstantial evidence. This evidence suggests that breastfeeding may particularly protect boys against high degrees of alexithymia, through i) possible sex-specific effects of responsive parenting aspects of breastfeeding, or ii) oxytocin in breast milk (e.g., Browne et al., 2010; Rilling et al., 2014). Results from previous studies showing that the effects of exogenous administration of oxytocin on social interactions were only positive in men, can be explained by the possibility that oxytocin has an inverted U-shaped dose response function (Feng et al., 2015). Because women have higher baseline levels of oxytocin compared to men, raising the oxytocin level in women “might displace them at the right of the maximum, decreasing brain activity” (Feng et al., 2015, p. 761).

The possibility that oxytocin in breast milk shapes the phenotype of the offspring would fit in the *Lactocrine Programming hypothesis* (Bartol, Wiley, & Bagnell, 2009; Miller, Wiley, Chen, Bagnell, & Bartol, 2013). Accumulating evidence from animal studies suggests that maternal hormones, ingested through breast milk, affect offspring development in a sex-specific manner (Angelucci, Patacchioli, Chierichetti, & Laureti, 1983; Casolini et al., 1997; Catalani et al., 2002; Hinde et al., 2014; Sullivan, Hinde, Mendoza, & Capitanio, 2011). Though oxytocin in breast milk, to our knowledge, is not yet directly investigated in relation to offspring development, sex-specific relations have been observed between offspring behavior and the stress hormone cortisol in breast

milk. For example, increased breast milk cortisol in monkeys was related to more confident temperament in male offspring (Sullivan et al., 2011), but to more nervous and less confident temperament in female offspring (Hinde et al., 2014). Additionally, increased milk cortisol was related to heightened Hypothalamic- Pituitary-Adrenal (HPA)-axis activity in female rodent offspring, but to decreased HPA-axis activity in male rodent offspring (Angelucci et al., 1983). Future research should investigate breast milk oxytocin to investigate sex-specific *Lactocrine Programming* effects on the offspring, including alexithymia.

It should be noted that, contradictory to our results, results from a large British study ($n > 13500$) suggested that breastfeeding had positive effects on emotional wellbeing, but in women only (Cable, Bartley, McMunn, & Kelly, 2011). Emotional wellbeing was measured with items such as “Are you easily upset or frustrated?”. A difference with our study was that the British study was conducted in two earlier cohorts (born in 1958 and 1970), where “most members of both cohorts were breastfed for < 1 months or not breastfed at all” (Cable et al., 2011, p. 654). As a result, a dichotomous variable was created that indicated whether the child received breastfeeding for ≥ 1 months (yes) or less than < 1 month (no). In our study, 27% of the infants was breastfed for less than one month, and thus most infants were breastfed for longer. It can be questioned whether a brief period of breastfeeding, like in the British cohorts, is associated with responsive parenting and/or sufficient exposure to breast milk hormones to have positive *Lactocrine Programming* effects for boys. For the girls, as they have higher baseline levels of oxytocin (Feng et al., 2015), this brief period may have been sufficiently short to show positive effects of oxytocin on later emotional well-being, but this hypothesis clearly needs testing.

The finding that the observed moderated mediation effect only held true for emotional eating, and not external eating (when adjusted for external eating, respectively emotional eating), adds to the literature showing that emotional and external eating, though highly interrelated ($r > 0.50$), should be conceived as distinct constructs with a different etiology and external validity (Van Strien, Herman, & Verheijden, 2009; Van Strien, Herman, & Anschutz, 2012; Van Strien, Kontinen, et al., 2016). The same holds true for our finding that our moderated mediation model was specific for alexithymia difficulty identifying feelings, similarly suggesting that alexithymia identifying and describing feelings are different constructs (see also, Tull, Medaglia, & Roemer, 2005).

Of note, alexithymia was assessed with a child version of the TAS, and not with the performance based LEAS (Levels of Emotional Awareness Scale; Lane et al., 1990). The LEAS asks participants to describe their anticipated feelings and those of another person for each of 20 scenes (vignettes) (Lane et al., 1996). Though the LEAS seems to outperform the TAS when it comes to the assessment of the alexithymia aspect difficulty describing feelings, the TAS outperforms the LEAS when it comes to the assessment of the alexithymia aspect difficulty identifying feelings (Lane et al., 1996). Hence, for our present research question, the TAS is the instrument of choice. It is nevertheless recommended to replicate the present study using the LEAS, to assess whether our present results are robust for differences in the measurement of alexithymia.

A strength of this study is that we covered a long-term longitudinal time-span of 15 years with a low attrition rate. Moreover, similar results were obtained with the child version of the DEBQ (DEBQ-C) at 12 years, and the 20-item adult version of the DEBQ at 16 years, which gives confidence in the robustness of the obtained results. A limitation of the current study is the use of self-reports. Participants may, for reason of social desirability, have disavowed their EE and external eating. Social desirability concerns, however, are not limited to studies that rely on self-reports. Social desirability may also affect behavior in direct tests of food intake, where specifically obese people may be motivated to avoid overeating, owing to the deviant status of obesity in our culture (Krantz, 1978). A problem with the measurement of alexithymia by self-report is that people who have difficulties to identify their feelings are asked to judge their own deficit in identifying feelings (Lane et al., 1990). Our

measure of breastfeeding was collected from maternal recall through interviews at 15 months of infant age. Maternal recall is found to be a valid and reliable estimate of breastfeeding initiation and duration, especially when the duration of breastfeeding is recalled after a short period (Li et al., 2008). However, a limitation of our breastfeeding measure is that it does not differentiate between exclusive breastfeeding versus mixed feeding (a combination of breastfeeding and formula feeding). Some research has suggested that the benefits of breastfeeding might be more pronounced for exclusively breastfeeding mothers (Edwards, Thullen, Henson, Lee, & Hans, 2015). As the amount of feedings not only predicts the amount of milk hormones ingested, but might also reflect responsive parenting styles, it is important for future research to not only take into account the duration of breastfeeding, but also the amount of feedings an infant receives per day.

Another strength of our study is that, as indicated by the distribution of parental and child measures at 15 months, the sample was representative of the Dutch population of families with young children (Van Bakel & Riksen-Walraven, 2002a, 2002b). However, due to constraints in time and resources, our sample was relatively small, with 104 children having complete data at age 12, and 91 children having complete data at age 16. Future research should replicate our findings in larger samples.

Another factor for future research to take into account is whether infants are fed on-demand or at scheduled intervals. The composition of human milk, i.e., low protein and fat content, is indicative of a continuous, on-demand, feeding schedule, as is seen in a multitude of tribal cultures (Jansen, de Weerth, & Riksen-Walraven, 2008). The practice of scheduling feeds has developed in Western civilization in order to accommodate working mothers, although on-demand breastfeeding is also seen. Breastfeeding on demand or at scheduled intervals may be particularly important when investigating the quality of parenting associated with these two types of breastfeeding. The ‘Start Healthy Feeding Guidelines for Infants and Toddlers’ of the American Dietetic Association recommend responsive parenting, recognizing and appropriately responding to infant hunger and satiety cues, including feeding on demand (Butte et al., 2004). Breastfeeding on demand might be especially related to responsive parenting, and subsequent less controlling and more responsive parental feeding and parenting practices later in childhood, when compared to breastfeeding at scheduled intervals, but this hypothesis needs further testing. This type of future research should also include attachment style, next to responsive parenting, as a mediator between breastfeeding practices and alexithymia. It has, for example, been found that breastfeeding duration predicts secure attachment at 24 months, irrespective of maternal sensitivity (Weaver et al., 2018), and also that features of anxious and avoidant insecure attachment styles are differentially related to separate facets of alexithymia (Oskis et al., 2013). Breastfeeding practices, including duration, amount and style of breastfeeding, could thus predict both responsive parenting and attachment style. Both, in turn, may independently predict alexithymia.

5. Conclusion

Breastfeeding in infancy may protect boys, but not girls, against emotional eating through its positive association with a better ability to identify feelings.

Conflicts of interest

Tatjana van Strien has a copyright and royalty interest in the Dutch Eating Behavior Questionnaire (DEBQ) and manual.

Role of funding source

This research was supported by a Sara van Dam Project Grant of the Royal Netherlands Academy of Arts and Sciences to Roseriet Beijers.

Funding for Tatjana van Strien and Laura Winkens was provided by the European Union FP7 MoodFOOD Project ‘Multi-country cOllaborative project on the rOle of Diet, FOOd-related behavior, and Obesity in the prevention of Depression’ (grant agreement no. 613598).

Acknowledgement

Tatjana van Strien wrote the first draft of the MS during her sabbatical-leave (autumn 2017) at the University of Valencia (Spain). She would like to thank Rosa María Baños Rivera for her hospitality and her roommate Marta Miragall Montilla for her helpful comments to an earlier version of the MS.
