Highlights from the ATLAS experiment

Iwona Grabowska-Bold on behalf of the ATLAS Collaboration$^a$,

$^a$AGH University of Science and Technology, Kraków, Poland

Abstract

This report provides an overview of the new results obtained by the ATLAS Collaboration at the LHC, which were presented at the Quark Matter 2018 conference. These measurements were covered in 12 parallel talks, one flash talk and 11 posters. In this document, a discussion of results is grouped into four areas: electromagnetic interactions, jet quenching, quarkonia and heavy-flavour production, and collectivity in small and larger systems. Measurements from the xenon-xenon collisions based on a short run collected in October 2017 are reported for the first time.

Keywords: ATLAS experiment, quark-gluon plasma, photon-induced processes, jet quenching, quarkonia production, heavy-flavour production, collectivity in small systems, xenon-xenon collisions

1. Introduction

In addition to proton-proton ($pp$) physics, the ATLAS Collaboration [1] participates in the heavy-ion (HI) programme which has been carried out at the LHC since 2010. Lead-lead (Pb+Pb) and proton-lead ($p$+Pb) collisions were provided at the centre-of-mass energies of 2.76 TeV, 5.02 TeV for Pb+Pb, and 5.02 TeV for $p$+Pb. In October 2017 a short period with xenon-xenon (Xe+Xe) collisions was taken. This opened up an opportunity of studying impact of different geometries on a broad range of observables. Moreover, the HI programme is supplemented with measurements in the $pp$ system, which serve as a reference to disentangle initial- from final-state effects.

2. Electromagnetic interactions in the QGP

The strong electromagnetic field associated with highly boosted nuclei at the LHC can be utilised to study the scattering of the quasi-real photons emitted coherently from the nuclei as they pass by next to each other. These are so-called Ultra-Peripheral Collisions (UPC). In the previous measurements of exclusive production of di-muon pairs [2] and light-by-light scattering [3], ATLAS already demonstrated that photon
fluxes emerging from Pb beams are well modelled by the STARlight generator. Also in those measurements, an acoplanarity distribution ($\alpha = 1 - \frac{\Delta \phi}{\pi}$, where $\Delta \phi$ is a distance in azimuth between final-state particles) was measured and proved to be powerful in discriminating between signal and background processes.

Very recently ATLAS has explored a potential of observing events from exclusive production of $\gamma \gamma \rightarrow \mu^+ \mu^-$ contributing to a sample of inelastic minimum-bias Pb+Pb collisions [4]. After evaluating and removing the contribution from background sources, the azimuthal angle ($\Delta \phi$) and transverse momentum ($p_T$) correlations between the muons are measured as a function of collision centrality.

Figure 1 shows the background-subtracted acoplanarity distribution in different centrality intervals. Each distribution is normalised to unity over its measured range. The $>80\%$ distribution with a significant contribution from UPC events is plotted in each panel for comparison. A clear, centrality-dependent broadening is seen in the acoplanarity distributions when compared to the $>80\%$ interval. The corresponding distribution from the $\gamma \gamma \rightarrow \mu^+ \mu^-$ MC samples is also shown. The MC $\alpha$ distributions show almost no centrality dependence, indicating that the broadening evident in the data is notably larger than that expected from detector effects. One potential source of modification is the final-state interaction of the produced leptons with the electric charges in the QGP. Assuming that the broadening of the $\alpha$ distribution results from transfers of a small amount of $p_T$ to each muon, in the 0–10% centrality interval that scale, assumed to be the RMS momentum transfer to each final-state muon in the transverse plane, is evaluated to amount to $70 \pm 10$ MeV.

3. Jet quenching

Using the large statistics of the 2015 Pb+Pb data, ATLAS finalised measurements of inclusive jet nuclear modification factor ($R_{AA}$) [5], as well as jet fragmentation functions [6]. Those results provide very detailed studies of inclusive jet production as a function of jet $p_T$, rapidity ($y$) and centrality in comparison to the reference $pp$ data collected at 5.02 TeV.

The $R_{AA}$ evaluated as a function of jet $p_T$ for two centrality intervals 0–10% and 30–40% is presented in the left panel of Fig. 2. The $R_{AA}$ value is obtained for jets with $|y| < 2.1$ and with $p_T$ between 80–1000 GeV. A clear suppression of jet production in central Pb+Pb collisions relative to $pp$ collisions is observed. In the 0-10% centrality interval, $R_{AA}$ is approximately 0.45 at $p_T = 100$ GeV, and is observed to grow slowly (quenching decreases) with increasing jet $p_T$, reaching a value of 0.6 for jets with $p_T$ around 800 GeV. In the same figure, the $R_{AA}$ values at 5.02 TeV are compared with the previous measurements at $\sqrt{s_{NN}} = 2.76$ TeV. The two measurements agree within their uncertainties in the overlapping $p_T$ region. The apparent reduction of the size of systematic uncertainties in the new measurement is possible thanks to large samples of $pp$ and Pb+Pb data collected during the same LHC running period.

Further insight in jet quenching can be obtained by studying jet fragmentation functions. The right panel of Fig. 2 presents a ratio of transverse jet fragmentation functions $D(p_T)$ in Pb+Pb to those extracted in $pp$ collisions as a function of jet fragment $p_T$ for three jet $p_T$ intervals. The $R_{D(p_T)}$ is above unity (enhancement) for low $p_T$ jet fragments, drops below unity for intermediate jet $p_T$ fragments (suppression) and becomes larger than unity again for jet fragment $p_T$ around 50 GeV. There is no significant difference between $R_{D(p_T)}$ for three jet $p_T$ intervals. A comparison between the data and the hybrid model calculation is also shown.
The model is able to describe the intermediate- and high-\( p_T \) regions for jet fragments, while it fails in the low-\( p_T \) region.

The ATLAS Collaboration performed a preliminary measurement of the angular distribution of charged particles around the jet axis in 5.02 TeV Pb+Pb and \( pp \) data [7]. The measured yields are defined as:

\[
R_{D(p_T)} = \frac{1}{N_{\text{jet}}} \frac{1}{2\pi r} \frac{d^2N_{\text{ch}}(r)}{drdp_T},
\]

(1)

where \( N_{\text{jet}} \) is the total number of jets, \( 2\pi rd\) is the area of the annulus at a given distance \( r \) from the jet axis, in pseudorapidity and azimuth respectively, \( dr \) is the width of the annulus and \( n_{\text{ch}}(r) \) is the number of charged particles within a given annulus. Results are presented as a function of Pb+Pb collision centrality, and both jet and charged-particle \( p_T \) in the left panel of Fig. 3. Ratios of \( D(p_T, r) \) distributions in Pb+Pb to those measured in \( pp \) collisions as a function of \( r \) for six charged-particle \( p_T \) intervals spanning values between 1.6–63.1 GeV in 0–10% centrality, and for jet \( p_T \) between 200–251 GeV are shown. The \( R_{D(p_T, r)} \) is above unity for all \( r \) values for charged particles with \( p_T \) less than 4 GeV. For these particles, \( R_{D(p_T, r)} \) grows with increasing \( r \) for \( r < 0.3 \) and is approximately constant for \( 0.3 < r < 0.6 \). For \( p_T > 4 \) GeV, \( R_{D(p_T, r)} \) is below unity and decreases with increasing \( r \) for \( r < 0.3 \) and is approximately constant for \( 0.3 < r < 0.6 \). The observed behaviour inside the jet (\( r < 0.4 \)) agrees with the measurement of the inclusive jet fragmentation functions [6], where yields of the low-\( p_T \) fragments are observed to be enhanced and yields of charged particles with intermediate \( p_T \) are suppressed. The measured dependence of \( R_{D(p_T, r)} \) suggests that the energy lost by jets through the jet quenching process is being transferred to particles with \( p_T < 4 \) GeV with larger radial distances.

ATLAS also measures inclusive jet mass (\( m \)) divided by the jet transverse momentum [8]. This fully-unfolded measurement of the jet structure is sensitive to the angular and momentum correlations of the jet constituents. These correlations can be used to study modifications of jets in HI collisions, where they provide complementary information to previously measured jet fragmentation functions.

The right panel of Fig. 3 presents \( R_{AA} \) as a function of \( m/p_T \) in 0–10% centrality for jet \( p_T \) between 126–158 GeV. For all centrality bins, these values have no significant dependence on \( m/p_T \). They are also observed to be consistent with the inclusive jet \( R_{AA} \).

A preliminary measurement of the balance between isolated photons and inclusive jets in \( p_T \) in 5.02 TeV Pb+Pb and \( pp \) data is performed. Photons with \( p_T \gamma > 63.1 \) GeV and |\( \eta \gamma | < 2.37 \) are paired inclusively with all jets that have \( p_T > 31.6 \) GeV and |\( \eta | < 2.8 \) in the event. The transverse momentum balance given by the jet-to-photon \( p_T \) ratio, \( \gamma_j \), are measured for pairs with azimuthal opening angle |\( \Delta \phi | > 7\pi/8 \). Distributions of the per-photon jet yield \( (1/N_j)(dN/d\gamma_j) \) are corrected for detector effects via a two-dimensional unfolding procedure and reported at the particle level for the first time.
Fig. 3. (Left) Ratios of $D(p_T, r)$ distributions in 0–10% Pb+Pb collisions to pp collisions as a function of angular distance $r$ for jet $p_T$ of 200 to 251 GeV for six $p_T$ selections [9]. (Right) Jet $R_{AA}$ as a function of $m/p_T$ in 0–10% centrality for jet $p_T$ between 126–158 GeV [8].

Figure 4 shows the measured $x_{J\gamma}$ distribution in five centrality intervals of Pb+Pb collisions for $p_T^{\gamma} = 63.1 - 79.6$ GeV in comparison to the $x_{J\gamma}$ distribution from pp collisions. The $x_{J\gamma}$ distributions in Pb+Pb collisions evolve smoothly with centrality. For peripheral collisions with centrality 50–80%, they are similar to those measured in pp collisions. However, in increasingly more central collisions, the distributions become systematically more modified. The $x_{J\gamma}$ distribution in the most central 0–10% events is so strongly modified that it is monotonically decreasing over the measured $x_{J\gamma}$ range and no peak is observed.

Fig. 4. Photon-jet $p_T$ balance distributions $(1/N_{\gamma}(dN/dx_{J\gamma}))$ in pp events (blue, reproduced on all panels) and Pb+Pb events (red) with each panel denoting a different centrality selection [7].

To probe physics of jet quenching in HI collisions with nuclei lighter than Pb, the transverse momentum asymmetry of dijet pairs and production rates of charged particles are measured by ATLAS with Xe+Xe collisions collected in October 2017 [10]. Figure 5 presents charged-hadron $R_{AA}$ as a function of $p_T$ for three centrality and $\langle N_{\text{part}} \rangle$ intervals along with the measurement from the Pb+Pb system. The $R_{AA}$ is compared between Xe+Xe and Pb+Pb data at 5.02 TeV. Even though they have different centralities, the $\langle N_{\text{part}} \rangle$ for the same $p_T$ intervals are comparable. The Xe+Xe data shows more suppression than the Pb+Pb data in more central collisions, and less suppression in more peripheral collisions.

Fig. 5. Charged-hadron $R_{AA}$ as a function of $p_T$ measured in Xe+Xe collisions 5.44 TeV (closed markers) and in Pb+Pb collisions at 5.02 TeV (open markers) [10].
4. Quarkonia and heavy-flavour production

The ATLAS Collaboration finalised a detailed study on prompt and non-prompt \( J/\psi \) and \( \psi(2S) \) production and suppression at high \( p_T \) in 5.02 TeV Pb+Pb and \( pp \) collisions [11]. The measurements of per-event yields, nuclear modification factors, and non-prompt fractions are performed in the di-muon decay channel for \( 9 < p_T^{\mu\mu} < 40 \) GeV in di-muon transverse momentum, and \( 2.0 < y_{\mu\mu} < 2.0 \) in rapidity. Strong suppression is found in Pb+Pb collisions for both prompt and non-prompt \( J/\psi \), as well as for prompt and non-prompt \( \psi(2S) \), increasing with event centrality. The suppression of prompt \( \psi(2S) \) is observed to be stronger than that of \( J/\psi \), while the suppression of non-prompt \( \psi(2S) \) is equal to that of the non-prompt \( J/\psi \) within uncertainties, consistent with the expectation that both arise from b-quarks propagating through the medium. Despite prompt and non-prompt \( J/\psi \) arising from different mechanisms, the dependence of their nuclear modification factors on centrality is found to be similar.

The left panel of Fig. 6 shows a \( p_T \)-dependence of the nuclear modification factor for prompt \( J/\psi \) mesons reconstructed via the muon channel at 5.02 TeV in the 0–20% centrality bin. The \( R_{AA} \) is at the level of 0.25 at \( p_T = 9 \) GeV and tends to increase slowly with \( p_T \). The ATLAS measurement at high \( p_T \) nicely complements the ALICE results for \( p_T < 12 \) GeV that are also shown on the same figure.

Recently the ATLAS Collaboration also evaluated elliptic flow of \( J/\psi \) with respect to the event plane in 5.02 TeV Pb+Pb collisions and presented preliminary results as a function of transverse momentum, rapidity and centrality [12]. It is observed that prompt and non-prompt \( J/\psi \) mesons have non-zero elliptic flow. Prompt \( J/\psi \) \( \nu_2 \) decreases as a function of \( p_T \), while non-prompt \( J/\psi \) \( \nu_2 \) is flat over the studied kinematical region. There is no dependence on rapidity or centrality observed. The right panel of Fig. 6 shows results for the \( \nu_2 \) as a function of \( p_T \) for prompt and non-prompt \( J/\psi \) as measured by ATLAS compared with inclusive \( J/\psi \) at \( p_T < 12 \) GeV, as measured by ALICE at 5.02 TeV, and prompt \( J/\psi \) at 6.5 < \( p_T < 30 \) GeV, by CMS at 2.76 TeV. Despite different rapidity selections, the ATLAS data is found to be in reasonable agreement with the ALICE and CMS data in the overlapping \( p_T \) region.

The ATLAS Collaboration also finalised a measurement of the production of muons from heavy-flavour decays in 2.76 TeV Pb+Pb and \( pp \) collisions [13]. Results are provided in the muon transverse momentum range \( 4 < p_T < 14 \) GeV and for five centrality intervals. Backgrounds arising from in-flight pi and kaon decays, hadronic showers, and mis-reconstructed muons are statistically removed using a template-fitting procedure. The heavy-flavor muon differential cross-sections and per-event yields are measured in \( pp \) and Pb+Pb collisions, respectively.

Figure 7 presents the heavy-flavour muon \( R_{AA} \) as a function of \( p_T \). The \( R_{AA} \) does not depend on \( p_T \) within the uncertainties of the measurement. The \( R_{AA} \) decreases between peripheral 40–60% collisions, where it is about 0.65, to more central collisions, reaching a value of about 0.35 in the 0–10% centrality interval. In Ref. [13] the azimuthal modulation of the heavy-flavor muon yields is also measured and the
associated Fourier coefficients \(v_n\) for \(n=2, 3\) and \(4\) are given as a function of \(p_T\) and centrality. They vary slowly with \(p_T\) and show a systematic variation with centrality which is characteristic of other anisotropy measurements, such as that observed for inclusive hadrons.

5. Collectivity in small and large systems

One active area of ongoing research is investigation of the nature of the long-range ridge observed in two-particle correlations in small collision systems such as \(pp\) and \(p+Pb\). To understand the multi-particle nature of the long-range collective phenomenon in those systems, the ATLAS Collaboration performed a measurement of symmetric cumulants \(s_{\nu_3}\{4\}\) and asymmetric cumulants \(a_{\nu_3}\{3\}\) which probe four- and three-particle correlations of two flow harmonics \(v_2\) and \(v_3\) in 13 TeV \(pp\), 5.02 TeV \(p+Pb\), and 2.76 TeV peripheral \(Pb+Pb\) collisions [14]. The large non-flow background from dijet production present in the standard cumulant method is suppressed using a method of subevent cumulants.

![Fig. 7. Heavy-flavour muon \(R_{AA}\) as a function of \(p_T\) for five centrality intervals in 2.76 TeV \(Pb+Pb\) collisions [13].](image)

Figure 7 shows a comparison of cumulants for the three collision systems. The three panels present the results for \(s_{\nu_3}\{4\}\), \(s_{\nu_4}\{4\}\), and \(a_{\nu_3}\{3\}\) for charged particles with \(0.3 < p_T < 3\) GeV. These results indicate a negative correlation between \(v_2\) and \(v_1\) and a positive correlation between \(v_2\) and \(v_4\). Such correlation patterns have previously been observed in large collision systems, but are now confirmed also in the small collision systems, once non-flow effects are adequately removed in the measurements. In the multiplicity range covered by the \(pp\) collisions, \(\langle N_{ch}\rangle < 150\), the results for symmetric cumulants \(s_{\nu_3}\{4\}\) and \(s_{\nu_4}\{4\}\) are comparable among the three systems. In the range \(\langle N_{ch}\rangle > 150\), \(|s_{\nu_3}\{3\}|\) and \(s_{\nu_4}\{4\}\) are larger in \(Pb+Pb\) than in \(p+Pb\) collisions. The results for \(a_{\nu_3}\{3\}\) are similar among the three systems at \(\langle N_{ch}\rangle < 100\), but they deviate from each other at higher \(\langle N_{ch}\rangle\). The results for \(pp\) data are approximately constant or decrease slightly with \(\langle N_{ch}\rangle\), while the \(p+Pb\) and \(Pb+Pb\) data shows significant increases as a function of \(\langle N_{ch}\rangle\). The similarity between different collision systems and the weak dependence of these observables on the \(p_T\) range and \(\langle N_{ch}\rangle\), largely free from non-flow effects, provide an important input for understanding the space-time dynamics and the properties of the medium created in small collision systems.

![Fig. 8. The \(\langle N_{ch}\rangle\) dependence of \(s_{\nu_3}\{4\}\) (left), \(s_{\nu_4}\{4\}\) (middle) and \(a_{\nu_3}\{3\}\) (right) in \(0.5 < p_T < 5\) GeV obtained for \(pp\) collisions (solid circles), \(p+Pb\) collisions (open circles) and low-multiplicity \(Pb+Pb\) collisions (open squares) [14].](image)
Using a data set of Xe+Xe collisions collected at 5.44 TeV, ATLAS measured flow harmonics with the scalar method (SP) and correlation techniques involving 2, 4 and 6 particles [15]. Centrality and $p_T$-dependence of the $v_n$ are studied. Figure 9 shows the $v_n$ harmonics integrated over the $0.5 < p_T < 5$ GeV range. The values are compared to those obtained for Pb+Pb and are shown as a function of centrality. The small differences are related to differences in the initial-collision geometry and subtle differences due to the system size. Detailed studies of scaling of $v_n$ and cumulants with $\langle N_{\text{part}} \rangle$ confirm the main source of $v_2$ to be the initial geometry, while geometry fluctuations to be the origin of differences for $v_n$ with $n > 2$.

ATLAS also measured the modified Pearson’s correlation coefficient to quantify correlations between flow coefficients and mean $p_T$ of charged particles in the event using 5.02 TeV Pb+Pb data [16]. It can be used in further experimental studies to understand the underlying mechanism of QGP dynamics and constrain theoretical models attempting to describe them.

6. Summary

The ATLAS Collaboration presented many new results covering Pb+Pb, p+Pb, pp, and also data from the new Xe+Xe system collected for the first time at the LHC. These measurements provide new information on electromagnetic interactions, the jet quenching, quarkonia and heavy-flavour suppression, as well as comprehensive results which provide further insight into the collectivity phenomenon of small collision systems.

This work was supported in part by Polish National Science Centre grant DEC-2016/23/B/ST2/01409, by the AGH UST statutory tasks No. 11.11.220.01/4 within subsidy of the Ministry of Science and Higher Education, and by PL-Grid Infrastructure.
