Young children integrate current observations, priors and agent information to predict others’ actions

Abstract

From early on in life, children are able to use information from their environment to form predictions about events. For instance, they can use statistical information about a population to predict the sample drawn from that population and infer an agent’s preferences from systematic violations of random sampling. We investigated whether and how young children infer an agent’s sampling biases. Moreover, we examined whether pupil data of toddlers follow the predictions of a computational model based on the causal Bayesian network formalization of predictive processing. We formalized three hypotheses about how different explanatory variables (i.e., prior probabilities, current observations, and agent characteristics) are used to predict others’ actions. We measured pupillary responses as a behavioral marker of ‘prediction errors’ (i.e., the perceived mismatch between what one’s model of an agent predicts and what the agent actually does). Pupillary responses of 24-month-olds, but not 18-month-olds, showed that young children integrated information about current observations, priors and agents to make predictions about agents and their actions. These findings shed light on the mechanisms behind toddlers’ inferences about agent-caused events. To our knowledge, this is the first study in which young children’s pupillary responses are used as markers of prediction errors, which were qualitatively compared to the predictions by a computational model based on the causal Bayesian network formalization of predictive processing.

Introduction

From a very young age, children are able to infer that some events are more probable than others. They use these inferences to form expectations about future events and show surprise when these events unfold differently. When 12-month-old infants see a container in which three identical objects and a single object move around before one of them exits the container, they look longer when the single object leaves the container rather than one of the majority objects [1]. A similar situation occurs when young children observe more or less probable
actions of another person. Xu and Garcia (2008) showed that infants as young as eight months of age look longer at a sample of colored balls if it is picked from a population of balls with mostly other colors, suggesting that they were expecting a different sample given the population [2]. In other words, if a population contains mainly red balls, infants expect sampling from the population to be random, resulting in a sample of mainly red balls. If this expectation is violated, this is reflected in an increased looking time. If, however, an agent consistently picks the same items from a population in a non-random way (e.g., all white balls from a predominantly red population), the observer might interpret this as an indication of a preference for a certain item. In a study by Kushnir, Xu, and Wellman (2010), 20-month-old children observed an agent picking five toys of the same type from a population box that held mostly toys from a different type [3]. When the toddlers were then asked to give the agent the toy he liked best, they often chose the toy that the agent picked before. If, on the other hand, the agent had picked the same toys from a population box in which the two types of toys were more evenly distributed, they picked this toy less often. These results suggest that infants infer preferences of others based on violation of random sampling.

Previous research has also shown that infants use probabilistic information to inform their predictions about others’ actions. For example, Henrichs and colleagues (2014) investigated whether goal certainty modulated action prediction patterns of 12-month-old infants [4]. In an eye-tracking paradigm, infants observed hands reaching towards one of three objects on the table, grasping the objects and placing them in a bowl. Infants performed earlier gaze shifts in the frequent condition when the hand reached for the same object in all trials as compared to the non-frequent condition, in which the hand reached for different objects across trials. These findings indicate that infants use probabilistic data to make predictions about others’ actions.

Recent accounts suggest that humans generate internal models to predict incoming information [5], [6]. This predicted input is compared to the actual input, and the difference (i.e., the prediction error) is used to update predictions. Previous studies have showed neural markers of prediction errors (e.g., [7], [8], [9], [10], [11]). Other studies suggest that prediction errors can also be assessed through measurements of pupillary responses, as these have been shown to correlate with prediction errors in a predictive-inference task [12] and with reward prediction errors [13] in adults.

Because pupillary responses occur involuntarily without explicit instructions, the method has also been valuable to unravel perceptual and cognitive processes in preverbal infants [14], [15]. Particularly, pupil dilation has been assumed to represent infants’ violations of expectations [16], [17]. For example, Addyman, Rocha, and Mareschal (2014) investigated time perception in infants by using a paradigm in which recurring targets were omitted [18]. Results of this study showed that 4- to 14-month-old infants showed increased pupil dilation to the absence of the targets at anticipated time intervals indicating a violation of their expectations of interval timing. In the present study, we take this approach one-step further and use infants’ pupillary responses as indirect behavioral markers of prediction errors in young children.

If young children predict other people’s actions in which the probability of events is represented, then we would expect to see increased pupil dilation when children observe improbable events. Looking times may be expected to increase in a similar way. Although they are indeed the most widely used measure of prediction violations [19], they are often measured over relatively long periods after stimulus presentation (e.g., > 12 sec in [20]; > 5 sec in [2]; > 6 sec in [21]). As such, it is difficult to distinguish between initial time-locked responses to the violation of predictions and cumulative responses that might reflect post-hoc processes [17]. The shorter time scale at which pupillary responses occur may provide unique insights into how different explanatory variables are used to form predictions over time.
In the current study, we investigated how 18-month-old infants and 24-month-old toddlers build up predictions about others’ actions. Do they, as suggested by previous studies, integrate information about prior probabilities and current observations to predict a subsequent event? Moreover, is the fact that the agent performing the action might have a bias also taken into account? In an experiment in which young children observed an agent performing a series of more or less probable sampling actions, we analyzed the changes in pupillary responses over trials to examine in a fine-grained manner how infants and toddlers build up predictions about an agent’s sampling actions. Here, it is important to note that differently from previous studies (e.g., [2], [21]) we measured the pupillary responses after each sampled outcome separately. This unique feature of our design allowed us to monitor how infants’ predictions and the resulting prediction errors evolved over time.

We created an experimental setting in which children observed a puppet drawing balls from a population box and placing them in a row in an open container one by one. The population box contained balls of two colors, with a ratio of 1:4. In the Minority-first condition, the puppet first performed a series of improbable actions by picking four colored balls of the minority color, before picking a ball in the majority color. In the Majority-first condition, the puppet performed a series of more probable actions by drawing four balls of the majority color, followed by one minority color ball.

Our computational approach allowed us to generate distinct hypotheses prior to data collection. We formalized three hypotheses to investigate how young children predict others’ sampling actions. These formalized hypotheses (of which the precise computational characterization is presented in S1 Appendix) provided us with a predicted pattern of prediction errors in all trials and conditions. We assume that in our experimental setup, there are three variables that are used to model the environment: (1) the previous observations (i.e. the balls that were sampled before), (2) the prior probabilities of an event (i.e. the probability of balls of a certain color being picked given the relative number of balls in a population), (3) the agent’s biases (i.e. tendency to pick a certain color). These variables increase in terms of level of complexity: whereas the first one is dependent on change detection, the second one relies on statistical inference, and the third one is based on processing of unobservable agent information. The hypotheses differ with respect to whether and how these variables are taken into account.

According to the first hypothesis, children make predictions solely based on the sample drawn so far. In other words, if a green ball were drawn from the population before, the best prediction of the next event would be that another green ball would be drawn. As evidence builds up, this prediction gets stronger, resulting in decreasing prediction errors over the course of trials. However, when the last ball differs from the previous ones, this should lead to an increase in prediction errors. As a result, over time, one would observe a decrease in pupillary responses in both the Minority-first and Majority-first conditions, as several balls of the same color are being picked repeatedly (see Fig 1A). However, when the last ball differs from the previous ones, one would expect the pupillary response to increase for the last sampling event as compared to the previous event in both conditions. In the first hypothesis, information about the fact that the ball was sampled from a population with a specific distribution or sampled by an agent who may have certain biases is assumed not to be taken into account.

The second hypothesis predicts that children do take probabilistic information about the population into account, but still ignore the information about the agent. This hypothesis entails that children use both prior probability and current observations to predict the next sampling event: a green ball picked from a mostly yellow population is improbable, but becomes slightly more probable after it happened a few times. Based on this hypothesis, one would expect the pupillary response for the first two trials to be large for the Minority-first condition. However, when balls of the same color are picked repeatedly, the pupillary responses...
Fig 1. The estimated size of the prediction error (and pupil dilation thereof) for the two experimental conditions as predicted by the computational models, based on Hypothesis 1 (A), Hypothesis 2 (B), and Hypothesis 3 (C).

https://doi.org/10.1371/journal.pone.0200976.g001
should decrease in the subsequent trials. Yet, when the last ball differs from the previous observations but it is more probable given the distribution of colors in the population box, we expected the pupillary responses to increase only slightly from the fourth to the fifth sampling event. In the Majority-first condition, on the other hand, one would expect the pupillary responses to be lower in the initial trials, as compared to the Minority-first condition, given that it is more probable to pick yellow balls from the given population box. However, because the last ball is different from the previous ones and it is less probable given the ratio of balls in the population box, we predicted a larger increase in the pupillary responses from the fourth to the fifth sampling event in Majority-first condition as compared to the Minority-first condition (see Fig 1B).

According to the third hypothesis, children do not only process the sampling actions as probabilistic events, but they also consider unobservable variables such as an agent’s bias while doing so. They integrate the prior probability and current observations in a way that includes agent characteristics as an explanatory variable that predicts observed actions. If an agent consistently performs an improbable action, then sampling might not be random but driven by some characteristics of the agent (e.g., a bias for picking a certain color). In terms of experimental findings, this hypothesis predicts that children show larger pupillary responses in the Minority-first condition, as compared to the Majority-first condition, during the first trials, because it is less probable to pick the minority balls repeatedly from the population box. Then, as several minority balls are selected in a row in the Minority-first condition, the joint probability of the events as a whole becomes so low that children will update their models. As a result, pupil dilation should decrease after the first few trials, as they will then assume that the agent deliberately selects balls in minority colors because of a picking bias and will expect the agent to keep doing this, consistent with this picking bias. However, as the last ball differs from the first four, their predictions based on the updated model will be violated and there will be a large increase in the pupillary responses again in this condition. On the other hand, in the Majority-first condition, there is no reason to reject the assumption that the agent samples randomly. Therefore, neither the fact that majority colors are being picked in a row nor the color of the last ball deviates from the previous ones is too surprising: the distribution of colors in the sample is consistent with the distribution in the population. If this is the case, the pupillary responses in the first few trials in Majority-first condition will be lower than in the Minority-first condition and they will only slightly increase in the last trial as compared to the previous trial, as the last balls differs from the previous observations (see Fig 1C).

Children’s predictions of other’s actions may become more precise over the course of development. For example, they might get more precise in representing statistical information, as they get older. It could also be that given the increased amount of social experience, they might become more proficient in recognizing others’ preferences. Indeed, developmental research on social cognition suggests that children’s attributions in social situations change as they accumulate more statistical evidence about agents in different situations through experience [22], [23]. For example, Ma and Xu (2011) investigated whether 24-month-old toddlers and 16-month-old infants use statistical information to infer that others might have preferences different from their own [24]. Although 24-month-olds first assumed that the experimenter would share their preference for a certain object, they were able to revise this assumption when the experimenter repeatedly chose another object, only if sampling appeared to be non-random. Whereas 24-month-old children were able to infer that the experimenter had a preference different from their own, 16-month-old infants showed weaker evidence for such an inference. As Ma and Xu (2011) argue, these findings suggest that the ability to reason about the subjective nature of preferences develops between 16 months and 2 years of age [24]. Given the previous literature, we included two age groups (i.e. 24- and 18-month-olds) in the
current experiment to investigate if the use of probabilistic and agent information in predicting others’ actions changes between 18 and 24 months.

Our modeling work provides us with an estimation of prediction errors in different trials and conditions. We then qualitatively compared these predicted patterns of results to the actual changes in pupil dilation for both age groups. With this, we provide more insight into the way in which children use prior probabilities, current observations and agent information to predict others’ actions, and how they revise their predictions over time.

Materials and methods

Participants

We tested 48 18-month-old infants (\(M = 18\) months 2 days; range 17 months 11 days–18 months 13 days) and 57 24-month-infants (\(M = 24\) months 1 day; range 23 months 4 days–24 months 15 days) for the study. Ten 18-month-olds and six 24-month-olds did not complete the testing session due to fussiness. There were 20 and 21 24-month-old-infants in the final statistical analyses in the Minority-first and Majority-first conditions, respectively. Participants were recruited from a database of volunteer families, and parents gave written informed consent for the study. Radboud University Nijmegen Social Science Faculty’s ethical committee approved the study. All children were born full-term and had no reported developmental delays. Participating families received a book or 10 Euros in return.

Stimuli

We created familiarization and test movies that showed animal hand puppets sampling colored balls from a population box and placing them one by one in an open container. The population box was transparent in front and had a white opaque cover on top in order to hide the sampling action. This part also served as an occluder to keep the puppets out of sight when they left the scene each time after they had drawn a ball from the population box. An opaque tube that was attached to the box led to the container on the left side of the box (see Fig 2A–2C).

Familiarization movie

In the familiarization movie (Fig 2A), a frog puppet popped up from behind the occluded part of the population box and started an introductory talk dubbed by a female voice. The puppet introduced itself and presented the population box, the tube and the container to the child. It then popped down to pick a ball from a population box filled with only blue balls before appearing again and moving towards the tube. The puppet’s hands and the ball were hidden behind the opaque part on top of the box until it put the ball into the tube. The puppet then quickly left the scene so that distraction was minimized during the measurement of the pupillary response in test trials. Immediately after the puppet disappeared, a rolling sound was played and the ball appeared on the left side of the container. The rolling ball was not shown to the viewer in order to ensure that participants did not see its color until it appeared in the container. The puppet then popped up again and explained that the balls roll all the way down to the end, in order to familiarize the child with the sudden appearance of the balls in the container. This process was repeated for five times and took 2.07 minutes in total.

Test movies

Four different animal hand puppets, dubbed by two male and two female voices, were used to depict the different conditions (see S1 File). Each trial in which the puppet picked one ball was
Fig 2. Snapshots from stimulus movies of the (A) Familiarization, (B) Minority-first condition, and (C) Majority-first condition.

https://doi.org/10.1371/journal.pone.0200976.g002
considered as a sampling event. One condition included five consecutive sampling events, in other words, five trials. We filmed each puppet for the Majority-first as well as for the Minority-first condition to counterbalance the conditions and the associated agents across participants. Test movies (see Fig 2B and 2C) were similar to the familiarization movie in terms of the set-up. However, the population box was now filled with balls in two different colors. In all movies, there was a 1:4 ratio of green and yellow balls.

As in the familiarization movie, the puppet gave a short introduction in which it told the participants its name, explored the set-up and explained that it would now pick a ball. Then, it popped down behind the white opaque part to pick a ball. At this point, the agent was not visible but a rumbling sound was presented while the balls moved inside the population box in order to indicate that the agent was picking a ball. Because the puppet was not visible when the balls were being picked, it was not obvious from the way in which the sampling action was performed whether it was random or not. The puppet then popped up from behind the opaque part, carried the ball, and put the ball into the tube. During this period, the ball that the puppet picked was still not visible to the participants. Immediately after the puppet left the scene, a rolling sound started lasting for 1400 milliseconds until the ball appeared on the left side of the container. The display of the sampled ball was shown for 4000 milliseconds. The puppet repeated the same process five times, picking balls one by one from the box. In the Minority-first condition, children observed the puppet drawing the minority color balls from the population box four times in a row before picking one majority color ball (see Fig 2B). In the Majority-first condition, the puppet drew four majority color balls followed by a minority color ball (see Fig 2C). We measured changes in pupil dilation after each sampling event. Majority-first and Minority-first conditions were shown twice to all participants. Although it was not a priori decision, as most participants got distracted quickly after observing the first five consecutive sampling events, only data for this first condition (i.e. Minority-first or Majority-first) were included in the analyses (see S2 File). In this way, we also ensured that carry-over effects that might occur due to the repetition of sampling sequences would not influence our data. The entire stimulus presentation consisted of the initial familiarization condition and both conditions shown twice (S2 File). One test movie lasted for 1.48 minutes and the entire stimulus presentation lasted for 8 minutes.

The stimulus material was edited in post-production using Final Cut Studio 3 (Apple Inc.). The movies were further edited using open source video editor software Kdenlive (version 0.9.6) to match the timing and the durations of each movie. As pupillary responses are sensitive to light effects, we paid utmost attention to luminance factors. In order to ensure that the movies had similar luminance values, we color-corrected the movies using Color software (version 1.5, Apple Inc.). The audio material for the movies was recorded and edited to match the pitch and speed of the audio material between movies using Audacity software (version 2.0.5).

**Experimental set-up and procedure**

The testing procedure was identical for both age groups. Eye movements were recorded with a corneal reflection eye-tracker (Tobii 120, Tobii Technology, Danderyd, Sweden) recording gaze data at 60 Hz using a 9-point calibration procedure. The procedure was repeated if seven or fewer calibration points were detected until data for at least eight calibration points was acquired.

To control for the external luminance effects, the natural lighting was entirely blocked and the room lights were on during the calibration and testing. In order to make sure that the environmental luminance was at a certain range during the measurements, we recorded the
environmental luminance during each testing using a custom-made device attached to the eye-tracker (Atlas Scientific ENV-RGB Color Detector Probe, version 1.6, combined with Arduino hardware), and the luminance values were extracted via Arduino software (version 1.0.5). The external luminance values were between 187–195 lux across testings. Participants were seated on their parent’s lap. All participants viewed the testing material at approximately 60 cm distance.

**Measures**

We measured the pupillary responses for each sampling event during the first 2000 ms after the sampled ball was visible in the container. Pupil data were analyzed using custom-made MATLAB scripts (MathWorks, Friedrichsdorf, Germany). The data were cleaned via several preprocessing steps. First, we screened for missing data points. If pupil dilation values were available for both eyes, then these were averaged in order to obtain one value per sample. In case of a missing value for one of the eyes, only the value from the other eye was used for the analyses. If the difference between the left and the right eye was larger than 1 (which is considered an indication of anisocoria: a condition characterized by unequal pupil sizes) or if average values were higher than two standard deviations from the mean, the data point was considered unreliable and registered as missing. Missing data points due to blinks were corrected using a linear interpolation algorithm, in which the maximum sample gap was set to 5. Following interpolation, the data were smoothed using median and moving average filtering in order to reduce the noise in the signal. If there were more than 60 missing samples in one trial of 2000 ms, the entire trial was excluded from the analyses. Pupil diameter changes were obtained by subtracting the average pupil diameter for each sampling trial from a fixed baseline period defined as the first 1000 ms from the start of each movie before the puppet appeared for the first time. Here, we aimed to find a window during the stimulus presentation when participants do not have any information regarding the sampled outcomes and the agent (it was not possible to have a period when the box was not visible). Because we reasoned that information such as the previous samples and the agents would modulate infant’s responses, we picked a baseline period during which none of this information was available. Finally, in case a value for one trial deviated more than two standard deviations from the overall trial average, it was considered an outlier and removed from further analyses. Before computing further statistical analyses on the data, we first conducted one sample t-tests against zero for each age group to ensure that there were indeed significant changes in pupillary responses as compared to the baseline level (cf. [16]). These analyses were informative as they provided a validation check for further statistical analyses testing the effects of task manipulations on pupillary responses.

**Results**

Measuring the pupillary responses after each sampled outcome separately allowed us to monitor how the children’s predictions evolved over time. One sample t-tests for 18-month-olds showed that overall, there was no significant change in pupillary responses as compared to the baseline level ($t(34) = 1.11$, $p = .27$). On the other hand, 24-month-olds showed significant increases in their pupillary responses as compared to baseline level ($t(50) = 4.18$, $p < .01$). Pupillary responses of the 24-month-olds and the 18-month-olds are illustrated in Fig 3 and Fig 4, respectively.

Because there was no difference in pupil response as compared to the baseline level in 18-month-olds, we did not compute further analyses for this age group. We reasoned that further analyses with this age group would be uninformative if not misleading given that there were no changes in pupillary responses as compared to the baseline level, which nullify
interpretations of the changes in pupil dilation as a function of different trials and conditions. As we did find a significant change in overall pupillary responses as compared to the baseline level in 24-month-olds, we focused our further analyses on this age group.

As we predicted differential response patterns for different combinations of trials given the differences in sampled outcomes, we examined the first two and last two trials separately. To examine participants’ initial responses to the probability of the outcomes, we first ran a repeated measures ANOVA with condition (Minority-first vs. Majority-first) as a between-subjects factor and first two trials (1 and 2) as a within-subjects factor. This analysis revealed a significant trial by condition interaction ($F(1, 42) = 4.80$, $p = .03$, $\eta^2 = 0.10$). As shown in Fig 3, this interaction was mostly driven by the larger difference in pupil dilation between conditions in the second trial. Still, follow-up t-tests showed that in the first trial, pupillary responses significantly differed between the Minority-first condition ($M = .22$, $SD = .20$) and the Majority-first condition ($M = .08$, $SD = .22$), $t(46) = 2.15$, $p = .04$. Similarly, in the second trial, the difference in pupillary responses between the Minority-first condition ($M = .25$, $SD = .18$) and
the Majority-first condition ($M = .01, SD = .29$) was significant, $t(40.61) = 3.47, p < .01$. These results show that in both trials, 24-month-old toddlers’ pupil dilation was larger when they observed an improbable sampling action as compared to a probable action. This finding supports the sub hypothesis of both the second and the third hypothesis: toddlers initially expected the samples to represent the distribution in the population box, thereby assuming that the agent samples from the box randomly. Moreover, as the joint probability of sampled outcomes became less probable with each sample in the Minority-first condition, the difference between the conditions became larger in the second trial.

When toddlers observed the agent consistently performing an improbable action (i.e., selecting minority color balls repeatedly), our third hypothesis would assume that this led them to revise their predictions: sampling might not be random, but biased towards a certain color because of some characteristics of the agent (e.g., the agent deliberately selects a certain color). After such a revision of their predictions, children would start expecting the agent to pick the minority color ball (which was previously considered improbable) and now would be surprised to see the majority color ball appear. On the other hand, when toddlers observed the agent consistently performing a more probable action (i.e., picking majority color balls), there would be no reason to revise the predictions. In order to test this assumption, we analyzed the differences in pupillary responses right before and after observing a change in the agent’s picking behavior. Using a repeated measures ANOVA with condition (Minority-first and Majority-first) as a between-subjects factor and trials (4 and 5) as a within-subjects factor, we analyzed the pupillary responses of the 24-month-olds in different conditions on the last two trials. As predicted according to the third hypothesis, data revealed a significant interaction between condition and trials ($F(1, 39) = 4.46, p = .04, \eta^2 = 0.09$). Follow-up t-test analyses showed that in the fourth trial, there was no significant difference in pupillary responses between the Minority-first condition ($M = .16, SD = .20$) and the Majority-first condition ($M = .07, SD = .28$), $t(43) = 1.21, p = .23$. However, in the fifth trial, pupil dilation in the Minority-first condition ($M = .27, SD = .16$) increased significantly, whereas this was not the case for the Majority-first condition ($M = .09, SD = .22$), $t(38.65) = 3.01, p < .01$. This finding is crucial, as it shows that toddlers combined observed outcomes and the information about the prior probability of an event with unobserved agent characteristics to predict the agent’s sampling actions over time. They thus showed increased response when their prediction was violated, which was assumed in the third hypothesis, but not in the other two hypotheses (see Fig 1C and Fig 3).

**Discussion**

In this study, we investigated how 18-month-old infants and 24-month-old toddlers build up predictions about others’ actions. We defined three explanatory variables that one might use when predicting the actions of another person: (1) previously observed events, (2) the prior probability of certain events, and (3) the characteristics of an agent. These three variables can be ordered with respect to their complexity. The first one only involves simple change detection, the second one uses statistical inference and the third one requires processing of unobservable agent information. Accordingly, we developed three hypotheses each including one relevant variable more than the previous, thus building up in their level of processing complexity. We tested these hypotheses in an experiment in which young children observed a puppet picking colored balls one by one from a population box. Their pupillary responses were measured after each sampling event and were assumed to be an index of prediction errors.

Our findings showed that 24-month-old toddlers integrate the prior probability and current observations as well as an agent’s biases to predict an agent’s sampling actions, and thereby supported the third hypothesis. Because we measured the pupillary responses after each
sampled outcome separately, we were able to monitor how their predictions and the resulting prediction errors evolved over time. Toddlers showed significantly larger pupillary responses when they observed an improbable as compared to a probable sampling action in the first two trials. This finding is in line with the assumption that young children form predictions based on the available statistical information: they predict that the distribution in a sample will reflect the distribution in the population from which they are drawn [21], [2] and are thus surprised when this prediction is violated.

Moreover, our findings suggest that repeated observations of the improbable outcome allowed toddlers to revise their predictions. They no longer assumed that the agent’s actions were random, but rather that they reflected a picking bias. As the agent consistently performed an improbable action, they expected the agent to keep showing this picking bias. However, when they observed that the last pick differed from the previous ones, this prediction was violated. The resulting prediction error caused a larger increase in their pupillary responses in the last trial in the Minority-first condition, as compared to the Majority-first condition. In the Majority-first condition, the overall sample resembled the distribution in the population box. Because this outcome was highly probable, the fact that the last ball had a different color did not lead to a strong increase in the pupillary response. These findings are in line with the idea that young children combine information about the prior probability of an event, observed outcomes and agent characteristics to predict an agent’s sampling actions.

Our findings suggest that 24-month-olds integrate agent information into their predictions. When a sample becomes highly improbable given the distribution in the population, toddlers no longer assume that the sampling is random. Rather, they assume that the sampling is driven by specific characteristics of the agent: for some reason, the agent deliberately selects one color. For example, this reason could be a preference for one color over the other or a task that has been given to this agent.

Whereas the 24-month-olds in our study showed clear indications of integrating previously observed events, prior probability information and the agent characteristics to form predictions, pupillary responses of 18-month-olds were inconclusive. Here, it is crucial to note that the lack of changes in pupil diameter as compared to the baseline, as it is the case for 18-month-old in the current study, is not evidence for absence of certain cognitive processes. In other words, the lack of meaningful pupillary responses in 18-month-old infants does not necessarily imply that 18-month-olds lack the abilities to attribute picking bias to agents. Nevertheless, previous studies have shown that even 10-month-old infants use statistical information to guide their inferences about others’ actions (e.g., [25], [20]). Because we observed no changes in 18-month-old infants’ pupillary responses as compared to baseline, we think that findings from this age group should not be interpreted. Accordingly, we can only speculate about the factors that might have led to the current findings.

Using looking time measures, Wellman and colleagues (2016) have shown that 10-month-old infants use probabilistic information to infer others’ preferences [20]. In this study, 10-month-old infants observed an agent sampling balls from a box. Infants who had seen this agent sampling balls from a minority color during a habituation phase looked longer when the sampled ball during the test event had a different color than when it had the same color. However, there was no such difference for the infants who had seen this agent sampling balls from a majority color during the habituation phase. The results are interpreted as evidence that a violation of expectations during the habituation phase, which only occurred when the agent sampled balls from a minority color, led the infants to attribute to the agent a preference for the sampled color.

Despite investigating a similar research question, there were theoretical and methodological differences between the study by Wellman and colleagues (2016) and the current one [20]. For
example, in the study by Wellman and colleagues (2016), a live actor sampled items from the population box [20]. Previous literature has shown that when infants observed a nonrandom sample, they expected that a person had drawn the sample but not a mechanical claw [24]. It might be that 18-month-old infants did not attribute a picking bias to the agents in the current study, thus, they did not show any differential pupil dilation response, as the agents were nonhuman. Moreover, here, we aimed to investigate infants’ predictions about others’ sampling actions and measured their pupillary responses as a behavioral proxy of predictions errors. Because pupil dilation is an involuntary response that occurs in a shorter time scale as compared to cumulative measures such as looking times, it would be reasonable to assume that current study tackles a different aspect of infant cognition as compared to previous studies. Whereas we measured immediate time-locked responses to the violations of predictions, previous studies focused on post-hoc processes observed in longer periods. Taken together, these theoretical and methodological discrepancies might account for differences in findings across studies.

One could also speculate that the 18-month-old infants’ models might not be advanced enough to integrate all three explanatory variables and the interactions between them. Alternatively, even if their internal models were advanced, they may not have generated very precise predictions resulting in low weighting on the prediction errors. For example, based on their internal model, infants may have a vague idea that what happened before is likely to happen again (cf. Hypothesis 1), but this idea might have been too weak to generate a prediction with high precision. Therefore, no or only a very weak prediction error would arise if this prediction is violated. Furthermore, it could even be the case that their internal models did not incorporate the causal link between the agent and the appearance of the balls, potentially preventing them from encoding the relevance of the color of the balls. Therefore, because of immature internal models, infants could have had weaker predictions or incorrect predictions all of which could explain the lack of overlap between their pupil response data and our hypotheses.

Predictive models of the environment might get more mature over the course of development, allowing children to make precise or detailed predictions about events. In daily life, children experience many events and most of the time there is a structure in these events. Certain events follow each other, which enables them to learn the regularities in the environment, and eventually the causal structure behind events [26]. Repeated experiences of certain events might allow them to improve their model of the world to make more precise or detailed predictions. With many of these experiences, a general model of the world develops. As children gather evidence on many different occasions involving a variety of agents and objects they choose, they collect more and more world knowledge. For example, they might see a friend repeatedly picking strawberries rather than pears or their father taking coffee rather than tea. All these experiences together might allow them to integrate new information in their world model efficiently. In other words, as their world knowledge improves, they become better at inferring the causes of others’ behavior without observing many occurrences. As a result, toddlers might need less information to form a certain prediction about other agents’ choices. Potentially, 24-month-olds have gathered the world knowledge necessary to be able to use the three explanatory variables in our experiment in the way specified in the third hypothesis. These findings shed light upon the mechanisms behind toddlers’ inferences about agent-caused events, as they suggest that from 24 months of age relevant information from the environment is used to form predictions about the causes of these events.

Conclusions
We presented formalized hypotheses of how young children combine perceptual, statistical and agent-related information to infer others’ biases. Our findings support the hypothesis that
24-month-old toddlers are able to integrate information about individual agents with information about previous events and prior probabilities to predict others’ actions. Moreover, we present an innovative approach in which young children’s pupillary responses are used as indirect behavioral markers of prediction errors. The pattern of pupillary responses in 24-month-olds, but not 18-month-olds, showed strong similarities with the prediction error patterns formalized by a predictive processing model. Our findings suggest that young children integrate information about current observations, prior probabilities and agents to predict others’ actions.
