We study the production of the exotic charged charmonium-like state $Z_{c}^{+}(3900)$ in $p\bar{p}$ collisions through the sequential process

$$\psi(4260) \rightarrow Z_{c}^{+}(3900)\pi^{\pm}, Z_{c}^{+}(3900) \rightarrow J/\psi\pi^{\pm}.$$ 

Using the subsample of candidates originating from semi-inclusive weak decays of $b$-flavored hadrons, we measure the invariant mass and natural width to be $M = 3902.6^{+5.2}_{-5.0}^{(\text{stat})}^{+3.3}_{-1.4}^{(\text{syst})}$ MeV and $\Gamma = 32^{+23}_{-21}^{(\text{stat})}^{+29}_{-7}^{(\text{syst})}$ MeV, respectively. We search for prompt production of the $Z_{c}^{+}(3900)$ through the same sequential process. No significant signal is observed, and we set an upper limit of 0.70 at the 95% credibility level on the ratio of prompt production to the production via $b$-hadron decays. The study is based on 10.4 fb$^{-1}$ of $p\bar{p}$ collision data collected by the D0 experiment at the Fermilab Tevatron collider.

I. INTRODUCTION
In high-energy hadron collisions, charmonium is known to be produced both promptly in QCD processes and nonpromptly in $b$-hadron decays, with well measured rates. For both $J/\psi$ and $\psi(2S)$ mesons the nonprompt fraction increases with transverse momentum but prompt production dominates in most of the studied $p_T$ range [1].

Much less information exists about the hadronic production of exotic multiquark states containing a charm quark and antiquark. The $X(3872)$—the most extensively studied exotic meson—is produced copiously in prompt $p\bar{p}$ interactions at $\sqrt{s} = 1.96$ TeV [2], and in $pp$ collisions at $\sqrt{s} = 7$ TeV [3] and $\sqrt{s} = 8$ TeV [4]. The fraction of the inclusive production rate of the $X(3872)$ mesons originating from decays of $b$-flavored hadrons ($H_b$) is found to be approximately 0.3 [3,4], independent of $p_T$. Evidence for prompt production of the $X(4140)$, another exotic candidate, was also reported by D0 [5]. The large prompt production rate of the $X(3872)$ has often been used as an argument against its identification as a weakly bound charm-meson molecule; see Ref. [6] for the latest discussion.

In Ref. [7], the D0 Collaboration presented the first evidence for production of the manifestly exotic charmoniumlike state $Z_{cc}^{+}(3900)$ in semi-inclusive weak decays of $b$-flavored hadrons in events containing a nonprompt $J/\psi$ and a pair of oppositely charged particles, assumed to be pions. That analysis considered the mass range $4.1 < M(J/\psi \pi^+\pi^-) < 4.7$ GeV that includes the $\psi(4260)$ state: $H_b \rightarrow \psi(4260) +$ anything, $\psi(4260) \rightarrow Z_{cc}^{+}(3900)\pi^+\pi^-$, $Z_{cc}^{+}(3900) \rightarrow J/\psi \pi^\pm$. This article presents an extension of that study to a search for prompt production of the $Z_{cc}^{+}(3900)$ through the sequential process $\psi(4260) \rightarrow Z_{cc}^{+}(3900)\pi^+\pi^-$, $Z_{cc}^{+}(3900) \rightarrow J/\psi \pi^\pm$. The event sample used in this analysis is approximately 50% larger than in Ref. [7] due to the use of an extended track finding algorithm optimized for reconstructing low-$p_T$ tracks.

II. THE D0 DETECTOR, EVENT RECONSTRUCTION, AND SELECTION
The D0 detector has a central tracking system consisting of a silicon microstrip tracker and a central fiber tracker, both located within a 1.9 T superconducting solenoidal magnet [8,9]. A muon system, covering $|\eta| < 2$ [10], consists of a layer of tracking detectors and scintillation trigger counters in front of a central and two forward 1.8 T iron toroidal magnets, followed by two similar layers after the toroids [11]. Events used in this analysis are collected with both single-muon and dimuon triggers. Single-muon triggers require a coincidence of signals in trigger elements inside and outside the toroidal magnets. All dimuon triggers require at least one muon to have track segments after the toroid; muons in the forward region are always required to penetrate the toroid.

The minimum muon transverse momentum is 1.5 GeV. No minimum $p_T$ requirement is applied to the muon pair, but the effective threshold is approximately 4 GeV due to the requirement for muons to penetrate the toroids, and the average value for accepted events is 10 GeV.

In $p\bar{p}$ collisions the $J/\psi$ is produced promptly, either directly or in strong decays of higher-mass charmonium states, or nonpromptly in $b$-hadron decays. Prompt mesons have a decay vertex consistent with the interaction point while those from the $b$ decays are displaced on average by $O(1 \text{ mm})$ as a result of the long $b$-hadron lifetime.

We reconstruct $J/\psi \rightarrow \mu^+\mu^-$ decay candidates accompanied by a pair of charged particles, assumed to be pions, with opposite charges and with $p_T > 0.7$ GeV. We perform a kinematic fit under the hypothesis that the muons come from the $J/\psi$ and that the $J/\psi$ and the two particles originate from the same space point. In the fit, the dimuon invariant mass is constrained to the world-average value of the $J/\psi$ meson mass [12]. The track parameters ($p_T$, position and direction in 3D) are readjusted according to the fit and are used in the calculation of the system’s transverse decay-path vector $\vec{L}_x$, the invariant mass $M(J/\psi \pi^+\pi^-)$, and the masses of the two $J/\psi\pi$ subsystems. Following Refs. [13,14], we select the larger mass combination as a $Z_{cc}^{+}(3900)$ candidate’s mass.

We select events in the $M(J/\psi \pi^+\pi^-)$ range $4.1–4.7$ GeV that includes the $\psi(4260)$ and excludes fully reconstructed decays of $b$ hadrons to final states $J/\psi h_1 h_2$ where $h_1$ and $h_2$ stand for a pion, a kaon, or a proton. We divide the data

FIG. 1. The $J/\psi \pi^+\pi^-$ decay length in the transverse plane for events in the range $4.2 < M(J/\psi \pi^+\pi^-) < 4.3$ GeV. The black filled circles show the distribution of events that satisfy the criteria for a displaced vertex. This subsample constitutes about $2/3$ of the nonprompt events. The distribution marked with blue triangles includes the prompt production and the remaining $1/3$ of the nonprompt events.
into two nonoverlapping samples: events with a displaced vertex, selected as in Ref. [7], and a complementary sample of “primary vertex” events. The criteria for the displaced vertex category are: the vertex of the $J/\psi$ and the highest $p_T$ track is required to be displaced in the transverse plane from the $p\bar{p}$ interaction vertex by at least $5\sigma$, the significance of the impact parameter in the transverse plane ($IP$) [15] of the leading track is required to be greater than $2\sigma$, the second track’s $IP$ significance is required to be greater than $1\sigma$, and the second track’s contribution to the $J/\psi + 2$

Left: events with a displaced vertex. Right: “primary vertex” events. Superimposed are the fits of a Breit-Wigner signal with fixed mass and width [16] (dashed blue lines), a Chebyshev polynomial background (dashed red lines), and their sum (solid blue lines).](image)

FIG. 3. The invariant mass distribution of \( J/\psi \pi^\pm \) candidates in three intervals of \( M(J/\psi \pi^\pm\pi^-) \), from top to bottom 4.4–4.5 GeV, 4.5–4.6 GeV, and 4.6–4.7 GeV. Left: events with a displaced vertex. Right: “primary vertex” events. Superimposed are the fits of a Breit-Wigner signal with fixed mass and width [16] (dashed blue lines), a Chebyshev polynomial background (dashed red lines), and their sum (solid blue lines).
FIG. 4. The \( Z^+_c(3900) \) signal yield per 100 MeV for the six intervals of \( M(J/\psi \pi^+ \pi^-) \): 4.1–4.2, 4.2–4.3, 4.3–4.4, 4.4–4.5, 4.5–4.6, and 4.6–4.7 GeV for (a) “displaced vertex” and (b) “primary vertex” selection. The points are placed at the bin centers.

### III. \( J/\psi \pi^\pm \) MASS FITS

We study the \( J/\psi \pi^\pm \) system in the vicinity of the \( Z^+_c(3900) \). We perform a binned maximum-likelihood fit of the \( M(J/\psi \pi) \) distribution to a sum of a resonant signal and an incoherent background in six intervals of \( M(J/\psi \pi^+ \pi^-) \): 4.1–4.2 GeV, 4.2–4.3 GeV, 4.3–4.4 GeV, 4.4–4.5 GeV, 4.5–4.6 GeV, and 4.6–4.7 GeV. The signal is represented by the \( S \)-wave relativistic Breit-Wigner function convolved with a Gaussian mass resolution. The \( Z^+_c(3900) \) mass and width are fixed to the values for the \( J/\psi \pi^\pm \) channels only (see Ref. [16]): \( M = 3893.3 \pm 2.7 \) MeV, \( \Gamma = 36.8 \pm 6.5 \) MeV. The D0 mass resolution at this mass is \( \sigma = 17 \pm 2 \) MeV. In these fits we allow negative values for the signal yield.

For the “displaced vertex” selection, the background is mainly due to weak decays of \( b \) hadrons to a \( J/\psi \) paired randomly with hadrons coming from the same multibody decay. For the “primary vertex” events, the main background is due to a promptly produced \( J/\psi \) combined with particles produced in the hadronization process. In both cases we use Chebyshev polynomials of the first kind to represent background. The fitting range limits are chosen so as to obtain an acceptable fit in a maximum range while avoiding areas where the total probability density function goes to zero. We choose the order of the Chebyshev polynomial to minimize the Akaike information test (AIC) [17]. For a fit with \( p \) free parameters to a distribution in \( n \) bins the AIC is defined as \( \text{AIC} = \chi^2 + 2p + 2p(p + 1)/(n - p - 1) \).

For the displaced-vertex subsample we choose a fourth-order polynomial, and for the “primary vertex” sample the choice is a fifth-order polynomial.

### IV. FIT RESULTS

The results of the fits are shown in Figs. 2 and 3 and summarized in Table I and in Fig. 4. The statistical significance of the signal is defined as \( S = \sqrt{-2\ln(L_0/L_{\text{max}})} \), where \( L_{\text{max}} \) and \( L_0 \) are likelihood values at the best-fit signal yield and the signal yield fixed to zero. In the case of a negative signal yield, \( S \) corresponds to the statistical significance of the depletion.

For the “displaced-vertex” subsample we see a clear enhancement near the \( Z^+_c(3900) \) mass for events in the range \( 4.2 < M(J/\psi \pi^+ \pi^-) < 4.3 \) GeV, consistent with coming from the \( \psi(4260) \) which has a mass of \( 4230 \pm 8 \) MeV [12], and a smaller excess in the ranges 4.5–4.6 GeV and 4.6–4.7 GeV. In the mass interval 4.3–4.4 GeV (and to

### TABLE I. \( Z^+_c(3900) \) signal yields, fit quality, and statistical significance \( S \) in intervals of \( M(J/\psi \pi^+ \pi^-) \) for events with a displaced decay vertex and for the complementary sample of “primary vertex” events, using the mass and width fixed at the PDG average values for the \( J/\psi \pi^\pm \) channel. \( M = 3893.3 \) MeV, \( \Gamma = 36.8 \) MeV.

smaller extent for 4.4–4.5 GeV) our fits show a negative, but not significant, yield of $Z^\pm_{d}(3900)$ events. There is no significant signal in the “primary vertex” subsamples in any $M(J/\psi\pi^+\pi^-)$ interval.

For the “displaced-vertex events” in the mass range $4.2 < M(J/\psi\pi^+\pi^-) < 4.3$ GeV we also perform a fit allowing the signal mass and width to vary. From this fit, shown in Fig. 5, we obtain our best measurement of the $Z^\pm_{c}(3900)$ signal: $M = 3902.6^{+5.2}_{-5.0}$ MeV, $\Gamma = 32^{+28}_{-21}$ MeV. The signal yield is $N = 364 \pm 156$ events, the fit quality is $\chi^2/ndf = 24.1/14$, and the statistical significance is $S = 5.4\sigma$.

V. ACCEPTANCE OF THE DISPLACED-VERTEX SELECTION

We obtain the acceptance of the “displaced-vertex” selection for $H_b$ decay events leading to $Z^\pm_{c}(3900)$ using candidates for the decay $B^0_d \rightarrow J/\psi K^+\pi^-$, assuming that the distributions of the decay length and its uncertainty for the $B^0_d$ decay are a good representation for the average $b$ hadron. Events are required to satisfy the same kinematic and quality cuts as applied above. We find the fitted numbers of $B^0_d$ decays $N_{\text{displaced}} = 12951 \pm 167$ and $N_{\text{primary}} = 6616 \pm 162$, respectively. The ratios of $N_{\text{primary}}$ to $N_{\text{displaced}}$ for $B^0_d$ and $Z^\pm_{c}(3900)$ events with the same topology should be the same, to the extent that the lifetimes of $B^0_d$ and $H_b$ are the same. With the systematic uncertainty discussed in the next section taken into account, the acceptance of the displaced vertex selection is $A = 0.66 \pm 0.02$.

VI. SYSTEMATIC UNCERTAINTIES

A. Mass and width

We assign an asymmetric systematic uncertainty of (0, +3) MeV to the mass measurement due to a bias in mass measurements of $b$ hadrons at D0. We assign the uncertainty on the mass and width due to uncertainty in the mass resolution as half of the difference of the results obtained by changing the resolution by $\pm 1\sigma$ to 15 MeV and 19 MeV. We assign uncertainties due to the background shape based on the differences in the results using the third, fourth, and fifth-order polynomial. The systematic uncertainties are summarized in Table II.

B. Signal yields

The uncertainty in the relative yields of prompt and nonprompt production of the $Z^\pm_{c}(3900)$ is dominated by statistical uncertainties. The systematic uncertainties are evaluated as follows.

(i) Mass resolution

We assign the uncertainty in the signal yields due to uncertainty in the mass resolution as half of the difference of the results obtained by changing the resolution by $\pm 1\sigma$ to 15 MeV and 19 MeV.

(ii) Trigger bias

Some of the single-muon triggers include a trigger term requiring the presence of tracks with nonzero impact parameter. Events recorded solely by such triggers constitute approximately 5% of all events. We assign a systematic uncertainty of $\pm 5\%$ to $N_{\text{displaced}}$ due to this effect.

(iii) Acceptance of the displaced-vertex selection

Our assumption of the equality of the displaced-vertex selection acceptance for the nonprompt $Z^\pm_{c}(3900)$ and for $B^0_d$ is based on the expectation of the equality of the average lifetime of the $b$-hadron parents of the $Z^\pm_{c}(3900)$ and that of the $B^0_d$. The world-average of the $B^0_d$ lifetime is 3% lower than the lifetime averaged over all $b$ hadron species [12]. This difference corresponds to a 1% difference in the acceptance. In addition, there may be small differences between different channels in the transverse momentum distributions of the parent $b$ hadrons and of the final-state particles. When the decay $B^0_d \rightarrow J/\psi\phi$ is used to estimate the “displaced-vertex” selection acceptance, the result is $A = 0.675 \pm 0.010$. We assign a $2\%$ uncertainty to the displaced-vertex acceptance to account for the differences between the $B^0_d$ decay and $H_b$ decays.

(iv) Signal model

We vary the fixed parameters [16] of the signal mass and width by ±2.7 MeV and ±6.5 MeV, respectively, corresponding to ±1σ.

(v) Background shape

For the “displaced vertex” selection, we assign a symmetric uncertainty based on the differences between the results obtained using the third, fourth, and fifth order polynomial. For the “primary vertex” selection, we assign an asymmetric uncertainty equal to the difference in the results using the fifth-order and fourth-order polynomial. The systematic uncertainties in the signal yield are summarized in Table III.

VII. EXTRACTING LIMITS ON PROMPT PRODUCTION RATES

Using results of the mass fits to the “displaced-vertex” and “primary vertex” subsamples and the above value of the acceptance of the displaced vertex selection, we can obtain acceptance-corrected yields of prompt and nonprompt production and their ratio. We determine the yield for the \( J/\psi\pi^\mp\pi^- \) mass range 4.2–4.3 GeV where the nonprompt signal is statistically significant.

The mass spectrum in the range 4.2–4.3 GeV in the “primary vertex” category shows no clear \( Z^\pm(3900) \) signal and a large background of about 5000 ± 70 events in the signal region. While there is no visible signal, we cannot exclude a yield comparable to the nonprompt signal.

In calculating the prompt-to-nonprompt ratio, we first obtain the total yield of the nonprompt production by dividing \( N_{\text{displaced}} \) by the acceptance \( A \). That gives \( N_{\text{nonprompt}} = 570 \pm 137 \) (stat + syst).

Of the above number, a fraction equal to \( 1 - A \) falls into the “primary vertex” category and must be subtracted to obtain the net number of prompt events, \( N_{\text{prompt}} = 149 - (1 - 0.66) \times 570 = -45 \pm 237 \). In calculating the uncertainty on the total prompt yield, we add the statistical and the systematic uncertainty components in quadrature.

We obtain the ratio \( r = N_{\text{prompt}} / N_{\text{nonprompt}} = -0.08 \pm 0.46 \). Assuming Gaussian uncertainties and setting the Bayesian prior for negative values of \( r \) to zero, we obtain an upper limit of 0.70 at the 95% credibility level.

VIII. SUMMARY AND CONCLUSIONS

Using the D0 run II data reconstructed with a dedicated extended-tracking algorithm optimized for low-\( p_T \) tracks, we have studied production of the exotic state \( Z^\pm(3900) \) in the decays of \( b \) hadrons to a \( J/\psi\pi^\mp\pi^- \) system with a subsequent decay to \( Z^\pm(3900)\pi^\mp \). The observation is consistent with the sequential decay of a \( b \)-flavored hadron \( H_b \rightarrow \psi(4260) + \text{anything}, \psi(4260) \rightarrow Z^\pm(3900)\pi^\mp \). We find a \( Z^\pm(3900) \) signal at a statistical significance of 5.4σ for events with \( 4.2 < M(J/\psi\pi^\mp\pi^-) < 4.3 \) GeV, and find its mass and width to be \( M = 3902.6^{+5.2}_{-5.0} \) (stat)\(^{+3.3}_{-3.4} \) (syst) MeV and \( \Gamma = 32^{+26}_{-21} \) (stat)\(^{+16}_{-26} \) (syst) MeV in agreement with world average values [12,16].

We searched for evidence of the prompt production of \( \psi(4260) \) with subsequent rapid decays to \( Z^\pm(3900)\pi^\mp \). In the absence of a significant signal we set an upper limit at the 95% credibility level on the ratio of prompt to nonprompt production, \( N_{\text{prompt}} / N_{\text{nonprompt}} < 0.70 \). This upper limit is significantly lower than that observed for \( X(3872) \), for which \( N_{\text{prompt}} / N_{\text{nonprompt}} \) is in the range two to three [3,4], and \( X(4140) \), for which \( N_{\text{prompt}} / N_{\text{nonprompt}} \approx 1.5 \) [5].

[10] η = −ln[tan(θ/2)] is the pseudorapidity and θ is the polar angle between the track momentum and the proton beam direction. φ is the azimuthal angle of the track.
[15] The impact parameter IP is defined as the distance of closest approach of the track to the pp collision point projected onto the plane transverse to the pp beams.
[16] Ref. [12] lists the Zc(3900) as a two-channel resonance and quotes average mass for the decays Zc(3900) → DD* and Zc(3900) → J/ψπ0. The mass values measured in the two channels differ by 11 MeV and the compatibility is ≈4 × 10−6. We choose to calculate the average mass and width for the J/ψπ0 channel only, using the PDG prescription for measurement averaging.
