Localised autonomic failure due to botulinum toxin injection

I read with great interest Mann's report of a patient receiving botulinum toxin injections for spasmodic torticollis who developed sialoceptasis and swelling of the parotid glands after each set of injections. 1 Local diffusion of the toxin and paralysis of the smooth muscle of the ducts was proposed as a possible underlying mechanism. 1

The inhibitory action of botulinum toxin is not confined to the neuromuscular junction. All the autonomic cholinergic fibres including the major secretomotor fibres to salivary glands are similarly blocked. Local diffusion and "chemodenervation" of the parotid glands leading to reduction of salivary flow and the development of chronic recurrent parotitis seems to be a more likely explanation for this patient's symptoms. Dickson and Shevky in 1923 showed that tympanic nerve-induced salivary flow was blocked by the toxin in cats. 2 In botulism, dry mouth is a common symptom, occurring in about 90% of patients. Dry mouth has also been reported in some 30% of patients after cervical injections for spasmodic torticollis. 3 Paradoxically, excessive salivation has long been known to occur in botulism. 4 A similar paradoxical effect on lacrimal glands producing watering of the eyes has been reported in patients receiving periorbital injections for blepharospasm or hemifacial spasm. 5 This paradoxical effect of the toxin on the "neuroglandular junction" remains unexplained. Increased saliva production may partly be responsible for parotid swelling after botulinum toxin injections in the patient reported.

Immunoglobulin treatment in human and experimental epilepsy

The paper of van Engelen et al 6 mentions some positive effects of intravenous immunoglobulin (IVIg) in the treatment of refractory epilepsy. No reference about our experience in that field is mentioned; however, in the medical literature reviewed by Van Engelen et al 6 in 1983, we successfully treated a patient with severe Lennox-Gastaut syndrome who still remains seizure-free. 7 Thereafter, in a first open study, 20 patients with Lennox-Gastaut syndrome and partial epilepsy were infused with IVIg. 8,9 This treatment gave excellent results in two patients, who were seizure free for months but relapsed afterwards although their seizures were less severe than before the infusions. In this open study, 15 patients have partially improved including eight with a pronounced decrease of seizures. It was concluded that IVIg treatment may be very helpful not only in West and Lennox-Gastaut syndromes, but also in partial epilepsy, including Rasmussen's syndrome. 9

At that time, however, all studies published about IVIg in refractory epilepsy were open designs—with the exception of that of Illm et al 10—which was a single-blind, cross-over trial—with different schedules and doses. Indeed the patients received from two to more than 10 infusions with doses ranging from 100 mg to 1 g/kg/perfusion and no relation was assessed between dose or schedule of IVIg and clinical responsiveness. An overview of the medical literature involving about 200 epileptic patients treated with IVIg showed a positive response to this treatment in around 50% of the patients. 7 Taking that into account, in 1989 we initiated the first double blind study to establish a dose of IVIg for treatment of epilepsy. 11 Sixty one patients were randomly assigned to receive either IVIg (n = 35) or a placebo (n = 25) at three different doses (100, 250, or 400 mg/kg/infusion). No dose effect was found (P = 0.31). The data for the whole study population showed an improvement in 52% of patients treated with IVIg (in accordance with previously reported open studies), compared with 28% in the placebo group; this positive trend was not significant (P = 0.09). When only the patients with partial epilepsy were assessed, a significant difference in favour of the IVIg treatment was found (P = 0.04) and this was confirmed in the subgroup of partial epilepsy with secondarily generalised seizures (n = 30) regardless of the dose (P = 0.04). Two patients became seizure-free (one with Lennox-Gastaut syndrome needs no further anticonvulsant medication). The other, who had

partial epilepsy, relapsed but is still better than before the IVIg.

The mechanisms of action are unknown. We found some relation between a lower serum IgA level and a better clinical response in the first study, 7 but could not confirm this correlation in the double blind study 11 although we noted a trend in the direction of a lower serum IgA. Infusions of IVIg in refractory epilepsy are well tolerated but the major problems related to this treatment concern its cost and the hazards of transmission of infectious diseases linked to blood derivatives. Immunoglobulins may be considered safe however, as their manufacturing procedures are known to inactivate human pathogenic viruses such as hepatitis A, B and C, and HIV. 7

1 Van Engelen BGM, Renier OW, Weezea CMR. Immunoglobulin treatment in human and experimental epilepsy. 1 Neurosurg Psychiatry 1995;57(supp):72-7
7 Van Engelen et al reply: We thank van Rijckevorsel and Delire for their interest in our paper on immunoglobulin treatment in human and experimental epilepsy. 2 Their point was that we did not mention their experience in that field. Our paper was an overview on some aspects of immunoglobulin effects in human and experimental epilepsies; it was not a review of the medical literature on immunoglobulin treatment in human epilepsies. We wrote a 1993 review on current immunoglobulin treatment in experimental epilepsies; we recognised their contribution in the field by citing three papers published by van Rijckevorsel and colleagues.
