THE CORRELATION BETWEEN URODYNAMIC AND CYSTOSCOPIC FINDINGS IN ELDERLY MEN WITH VOIDING COMPLAINTS

From the Department of Urology, University Hospital Nijmegen, Nijmegen, The Netherlands

ABSTRACT

Purpose: We evaluated the urethrocystoscopic findings and results of urodynamic studies in elderly men with voiding complaints.

Materials and Methods: A total of 492 consecutive patients with voiding complaints underwent a standardized screening program, including transrectal ultrasonography of the prostate, urodynamic investigations with pressure-flow study analysis and flexible urethrocystoscopy.

Results: A significant correlation was found between bladder trabeculation and grade of bladder outlet obstruction. Detrusor instability correlated significantly with grade of trabeculation. Grade of obstruction showed a clear correlation with prostatic occlusion of the urethra and the presence of a middle lobe at cystoscopy.

Conclusions: The findings at urethrocystoscopy correlate well with those of urodynamic investigations.

KEY WORDS: urodynamics, cystoscopy, prostate

For many years the diagnosis and management of voiding complaints in elderly men were straightforward. Surgical techniques for removing the obstructive prostatic tissue relieved symptoms in most men and much debate focused on the relative value of open prostatectomy versus transurethral resection. However, with the advent of medical and less invasive modalities for the treatment of bladder outlet obstruction, it has become necessary to know more about the etiology and pathology of the disease. It is well known that evaluation and treatment of voiding complaints in elderly men are primary endeavors of the urologist and lead to the surgical procedures listed in the urological armamentarium. Also, voiding complaints in elderly men are most frequently caused by benign prostatic hyperplasia (BPH), which develops with increasing frequency as men age. The resulting prostatic growth has a critical role in altering voiding, which results in significant (pathological) changes in the urinary tract of some patients and symptoms alone in others. On the other hand, the role of BPH in the voiding dysfunction experienced by elderly men is often unclear. Hyperplasia may be associated with striking lateral lobe enlargement but symptoms may be negligible if the degree of obstruction is not severe. Conversely, BPH may be associated with a relatively small prostate and marked obstructive symptoms if the obstructing tissue originates exclusively within the central zone or periurethral gland area. Although the pathophysiology of BPH and its effect on the bladder wall are not completely understood, we agree that when the bladder passes through the stages of irritability, compensation and decompensation outlet obstruction may occur. In response to outlet resistance, hypertrophy of the detrusor muscle begins and trabeculation may develop.

Urethrocystoscopy provides information on the cause, size and severity of obstruction, patency of the bladder neck, prostatic occlusion of the urethra and estimated prostatic size. The gold standard to measure bladder outlet obstruction is by urodynamic investigations with pressure-flow study. Although the diagnosis and treatment of BPH are common subjects, only limited information is available regarding the correlation between urethroscopic findings and urodynamic studies. Turner-Warwick et al concluded that the endoscopic appearance of trabeculation in men is usually associated with a thick walled bladder but it is not diagnostic of obstruction, and that the most common correlation is noted with unstable detrusor function, which may or may not be associated with obstruction. Andersen and Nordling concluded that urethrocystoscopy provides good information on the site and severity of obstruction. Recently, Madsen and Bruskewitz concluded that urethrocystoscopy has a limited role in the evaluation of BPH. However, they mentioned that available data suggest that bladder trabeculation in BPH is a predictor of treatment outcome, and that cystoscopy might be performed before invasive therapy to guide the urologist in choosing an operative approach.

We evaluated the findings of urethrocystoscopy compared to those of the preceding urodynamic studies to determine whether trabeculation and prostatic enlargement indicate bladder outlet obstruction, whether an enlarged middle lobe correlates with increased outlet resistance, and whether there is a relationship between bladder trabeculation and instability.

MATERIAL AND METHODS

A total of 492 consecutive patients with voiding complaints underwent a standardized screening program, including history, physical and digital rectal examinations, biochemistry studies (prostate specific antigen), urinalysis and culture, urine cytology, transrectal ultrasonography of the prostate, urodynamic investigations and flexible urethrocystoscopy. Prostatic size was determined using an ultrasound scanner with a 7.5 MHz. transrectal probe. The prostate was imaged from base to apex, documenting the presence of prostatic abnormalities and measuring the prostatic volume using the planimetric method. Urodynamic investigations were performed with an 8F transurethral lumen catheter and an 8F transrectal catheter, both equipped with a microtip pressure sensor. Before cystometry the bladder was emptied through the lumen of the transurethral catheter to quantify residual
urine after free uroflowmetry. The pressure sensors were set
at zero to atmospheric pressure before introduction. The
bladder was filled with water at 20°C and a filling speed of 50
ml per minute with the patient supine. Filling was stopped
when the patient expressed a strong urge to void, and mic­
turition while standing was allowed in private. The digitally
stored data were analyzed with equipment developed at our
department.

To obtain useful information from the pressure-flow study
curves, it was necessary to relate detrusor pressure to the
corresponding flow. To quantify the grade of outlet obstruct­
ion, the concept of the linear passive urethral resistance
relation, connecting minimal urethral opening pressure with
pressure at maximum flow, was used. Classes 0 and 1 of this
scale indicate no, classes 2 and 3 moderate, and higher
classes severe bladder outlet obstruction on urodynamic
study. Another method of grading bladder outlet obstruction
is with the urethral resistance factor, which is calculated
based on the point of maximum flow and corresponding
detrusor pressure. A urethral resistance factor value of more
than 29 cm. water indicates obstruction. Finally, the minimal
urethral opening pressure and theoretical urethral lumen
were calculated on the basis of the passive urethral resis­
tance relation curves, adjusted to the lower pressure area of
the pressure flow graph. The investigations were completed
by urethrocystoscopy.

The studies were done with the patient under local anes­
thesia. A flexible urethrocystoscope was used to evaluate the
entire bladder surface with special attention to bladder trabecu­
culations, which were classified as 0—none, 1—slight to
moderate, 2—severe and 3—severe with formation of
(pseudo)diverticula. Moreover, the appearance of the bladder
neck was described, and the degree of prostatic occlusion of
the urethra as well as the distance from the bladder neck to
the verumontanum were reported. Prostatic occlusion was
graded as 1—no, 2—moderate and 3—severe obstruction (fig.
1). Also the presence of a high and narrow bladder neck, and
a middle lobe was documented. Patients with urethral stric­
tures, prostate cancer or bladder abnormalities, such as blad­
der stones, were excluded from this study since these dis­
eases were believed to be the predominant cause of the
symptoms. For statistical analysis the Kruskal-Wallis and
chi-square correlation tests were used.

RESULTS

Mean patient age was 64.8 years (range 42 to 89) and the
prostate volumes ranged from 13 to 127 cc (mean 44.7 ± 20).
The grade of trabeculation was correlated with the clinical
parameters (table 1). Of the patients 12% had grade 0, 65% grade 1, 23% grade 2 and 7% grade 3 trabeculation. An
increase in trabeculation was noted in patients with larger
prostates. The total International Prostatic Symptom Score
(I-PSS) also increased slightly with higher grades of trabecu­
culation but without significant statistical correlation. On
the other hand, the filling component of I-PSS (the total score of
questions 2, 4 and 7) correlated weakly with trabeculation.
Also the maximum flow rate and post-void residual volume
showed a significant correlation with trabeculation. Uroflow­
metry results for the entire group demonstrated an average
maximum flow of 10.8 ± 5.8 ml per second with a post-void
residual volume of 70 ± 114 ml. There was a decrease in
maximum flow rate and an increase in the post-void residual
volume with higher grades of trabeculation.

The pressure-flow study parameters also showed significant
 correlations with trabeculation. With increasing grade of
trabeculation, detrusor pressure at maximum flow rate,
linear passive urethral resistance relation, urethral resis­
tance factor and minimal urethral opening pressure in­
creased (table 2). These correlations were statistically signifi­
cant. Other urodynamic parameters, such as the theoretical
urethral lumen, correlated significantly with inverse relation
with trabeculation. The cystometric capacity worsened with
increasing grade of trabeculation but this was not statisti­
cally significant. The relationship between grade of bladder
trabeculation and severity of bladder outlet obstruction is
shown in figure 2. We conclude that an increase in trabecu­
lation significantly correlates with an increase in bladder
outlet obstruction.

D detrusor instability was noted in 74 patients, and there
was good correlation between the grade of trabeculation and
detrusor instability (table 3). Of the patients 112 had a small
middle lobe and 48 had a large middle lobe. With the pres­
ence of a middle lobe, there appeared to be a tendency to­
wards increased grade of obstruction according to linear pas­
sive urethral resistance relation (fig. 3). The correlation
between prostate size, measured by transrectal ultrasound,
and trabeculation was less pronounced (fig. 4). However,
there appeared to be good correlation between grade of pros­
tatic occlusion, estimated at urethrocystoscopy, and grade of
outlet obstruction (p <0.0001, fig. 5).

DISCUSSION

Among the urological community it is generally believed
that voiding complaints in elderly men are caused most fre­
quently by BPH. Indeed, for many years the diagnosis and
management of this disease aimed at removing the obstruc­tive prostative tissue. During the last years, however, research
has led to the understanding that so-called BPH is not a
single disease but one characterized by heterogeneity. The
pathophysiology of the disease varies in the nature of the
mechanical obstruction, for example lateral, middle or trilo­
bar hyperplasia, the degree of dynamic obstruction and the

![Fig. 1. Cystoscopic appearance of bladder trabeculation (0—none,
1—slight to moderate, 2—severe and 3—severe with formation of
diverticula) and prostatic occlusion (1—no, 2—moderate and 3—
severe obstruction).](image-url)
response of the detrusor musculature. The rings of Hald provided a sound basis in which the pathophysiology is divided into 3 parts: lower urinary tract symptoms, prostate size and bladder outlet obstruction.\(^\text{14}\) Despite the existence of an increasing number of reports on the relationship between prostate size and obstruction, a defined correlation between the pathophysiological components remains unproved.\(^\text{15-17}\)

Does there really exist a good correlation between bladder trabeculation and the results of pressure-flow studies? Is the finding of trabeculation correlated with worsening bladder function? Does trabeculation correlate with bladder instability? We showed unequivocally that a correlation exists between the presence of a middle lobe and the grade of bladder outlet obstruction. Moreover, the obstruction classification of the prostate at cystoscopy seems to correlate even better with grade of bladder outlet obstruction than measurement of prostate volume alone. We agree with Andersen and Nordling that urethrocystoscopy also provides good information on the site as well as the hydrodynamic severity of organic infravesical obstruction.\(^\text{9}\) Indeed, the urodynamic parameters of bladder outlet obstruction, judged by the pressure flow parameters, were significantly correlated with the urethrocystoscopic findings of prostatic occlusion of the urethra and the presence of a middle lobe.

At cystoscopy, many urologists attempt to evaluate the degree of obstruction by assessing bladder trabeculation. However, to our knowledge no studies have shown a significant association between bladder trabeculation and severity of obstruction.\(^\text{9, 18}\) In the male patient the detrusor muscle

Values are given as number of patients (percent).
reacts to outlet obstruction in a variety of ways and not all
detrusors are equal. The presence of bladder trabeculation
and (pseudo)diverticula has traditionally been regarded as a
sign of compensatory bladder hypertrophy. Chappie and
Turner-Warwick concluded that the endoscopic appearance
of trabeculation in the male patient is usually associated
with a thick walled bladder but neither is diagnostic of ob­
struction.19 Our results show that there is good correlation
between grade of trabeculation and grade of bladder outlet
obstruction. For the individual patient, however, one cannot
make the same conclusion. Moreover, we are aware that
grading of trabeculation is physician dependent. Some re­
searchers stated that trabeculation appeared to correlate
with collagen deposition, rather than muscular hypertrophy,
although both of these processes appear to occur in ob­
structed bladders.20,21 However, sequence of hypertrophy
and collagen deposition is not clear, and some discrepan­
cies in the findings related to the presence or absence of muscle
hypertrophy and collagen deposition may reflect the stage of
development of detrusor changes in relation to obstruction.
In contrast with the findings of Andersen and Nordling,9 our
study shows a clear correlation of detrusor instability with
grade of trabeculation.

We agree with Elbadawi et al that it remains to be deter­
mined whether overactivity and trabeculation represent a
cause and effect relationship or are independent manifesta­
tions of the same process that initiates structural changes in
the aging detrusor in general.22 They attempted to define a
structural and urodynamic grouping of patterns with prog­
nostic, predictive potential in various forms of voiding dys­
function. There seems to be good correlation between the
ultrastructural features of the structural patterns and
matching urodynamic findings. Widespread degeneration of
muscle cells and axons is proposed as the structural correlate
of impaired detrusor contractility in the aging detrusor.

The lack of a strong relationship between urological symp­
toms, and the anatomical and physiological measures of BPH
severity has been described by others.23,24 Our study con­
firmed this presumption only partially. It appeared that the
filling component of the symptom scores correlated signifi­
cantly with grade of bladder trabeculation. An explanation
for this finding may be that with an increase in bladder outlet
obstruction an increase in the number of patients with blad­
er instabilities can be found.

Finally, what is the implementation of our findings in daily
clinical practice? A considerable number of urologists still
depend on cystoscopic rather than urodynamic findings in
the diagnosis of bladder outlet obstruction because they do
not have urodynamic equipment at their disposal or are not
used to performing urodynamics in patients with BPH. How­
ever, bladder outlet obstruction is present in approximately
15% of patients with normal cystoscopic findings (fig. 2, A).
On the other hand, if severe trabeculation is present, approxi­
mately 8% of the patients have no obstruction at all.

CONCLUSIONS

Generally the findings at urethrocystoscopy correlate well
with the results of urodynamic investigations. For the indi­
vidual patient, however, one cannot make the same conclu­
sion. In response to several different etiological factors, the
bladder wall undergoes distinct morphological changes that
are readily recognized macroscopically as trabeculation.
Whether trabeculation is associated with bladder dysfunc­
tion with irreversible changes at the cellular level or simply
a sign of reversible compensation due to bladder obstruction
remains unclear.

URODYNAMIC AND CYSTOSCOPIC FINDINGS IN ELDERLY MEN WITH VOIDING COMPLAINTS

EDITORIAL COMMENT

This significant article contains important data. The study clearly documents a correlation between cystoscopic appearance (grade of trabeculation and grade of prostatic urethral obstruction), and urodynamic indexes of obstruction, detrusor instability and low compliancy. The implication of these findings is that cystoscopic appearance can predict obstruction and detrusor instability but the authors have not really shown this to be true. They did not evaluate impaired detrusor contractility. It is possible that the cystoscopic appearance will also correlate with impaired detrusor contractility. If so, then cystoscopy does nothing more than correlate with all of the underlying pathophysiological conditions that account for symptoms in prostatism, that is, obstruction, instability, low compliance and impaired contractility. How, then, is this clinically useful? What does it mean for an individual patient if cystoscopy is normal or there is no obstruction? What is the clinical role of these diagnostic procedures? Are they useful or predictive of therapeutic outcomes? We still need much more about this most common affliction of men.

REPLY BY AUTHORS

Currently many studies are being conducted to investigate the pathophysiology of BPH and its effect on the bladder wall. It is generally accepted that the best test to measure bladder function is urodynamic investigation with pressure-flow studies. However, many urologists still rely on clinical experience to diagnose bladder outlet obstruction as “measured” by the results of symptom scores, clinical examination and the findings at urethrocystoscopy. Indeed, in general the urethrocystoscopic findings correlate well with the urodynamic results. For the individual patient, however, one cannot make the same conclusion. Therefore, we believe that the value of urethrocystoscopy is only limited. It should not be used to diagnose bladder outlet obstruction but primarily to exclude bladder pathology and to decide among interventional approaches (transurethral incision or resection of the prostate, suprapubic prostatectomy and so forth).

It remains unclear whether trabeculation is associated with bladder dysfunction with irreversible changes at the cellular level. Recently, Rosier et al. analyzed detrusor contraction power in patients with lower urinary tract symptoms and bladder outlet obstruction and concluded that maximum contraction during micturition is affected by the grade of bladder outlet obstruction. Because of this finding and the fact that the correlation between the cystoscopic appearance with bladder outlet obstruction is limited, we believe that the cystoscopic appearance will correlate only poorly with impaired detrusor contractility.
