The effects of 5-fluorouracil and interferon-\(\alpha\) on early healing of experimental intestinal anastomoses

JWD de Waard*, T Wobbes, BM de Man, CJ van der Linden and T Hendriks

Department of Surgery, University Hospital Nijmegen, Nijmegen, The Netherlands.

Summary

The continuing search for effective adjuvant therapy after resection of intestinal malignancies has prompted a growing interest in both immediate post-operative regional chemotherapy and the combination of 5-fluorouracil (5-FU) and interferon-\(\alpha\) as drugs of choice. We have compared the effects of both compounds, alone and together, on early healing of intestinal anastomoses. Four groups \((n=26\) each) of rats underwent resection and anastomosis of both ileum and colon: a control group and three groups receiving intraperitoneal 5-FU, interferon-\(\alpha\) or both on the day of surgery and the next 2 days. Animals were killed 3 or 7 days \((n=10\) each) after operation in order to measure anastomotic strength and hydroxyproline content. The remaining six animals in each group were used to study anastomotic collagen synthetic capacity at day 3. Three days after operation, ileal anastomotic bursting pressure was lowered by 37\% in the 5-FU/interferon-\(\alpha\) group \((P = 0.0104)\). At day 7, anastomotic breaking strength was reduced significantly in ileum \((P = 0.0221)\) and colon \((P = 0.0054)\) of the 5-FU/interferon-\(\alpha\) group and in colon of the interferon-\(\alpha\) group \((P = 0.0221)\). Collagen synthetic capacity was strongly suppressed by 5-FU but not by interferon-\(\alpha\). However, no differences in anastomotic hydroxyproline content were observed between groups at both days 3 and 7. Thus, post-operative use of interferon-\(\alpha\), in particular in combination with 5-FU, may be detrimental to anastomotic repair in the intestine.

Keywords: anastomosis; collagen; fluorouracil; interferon-\(\alpha\); intestine

Despite the high resectability rate and general improvement in surgical therapy, nearly half of all patients with colorectal cancer will eventually die from recurrent disease. Candidates for post-operative adjuvant therapy are patients at risk for disease relapse, as judged by clinical evaluation, surgical examination and pathological examination of resection specimens. In general, safe and effective adjuvant therapy would be highly desirable in patients with Dukes' stage B2 and C colon carcinoma, which constitute 60 - 70\% of the population presenting with colorectal cancer.

Over the last three decades numerous studies have shown little or no survival benefit, although small but significant clinical improvement, from post-operative chemotherapy using 5-fluorouracil (5-FU) as the primary agent (Kemeny et al., 1993; Moertel, 1994). Presently, preclinical and clinical protocols aim to increase the activity of 5-FU-based adjuvant therapy. The optimal manner in which 5-FU should be administered still remains to be determined. There appear to be excellent reasons to start treatment immediately after operation (Harris and Mastrangelo, 1991) and to administer drugs intraperitoneally (Cunliffe and Sugarbaker, 1989). Indeed, a survey of ongoing European trials shows increasing interest in treatment modalities that include immediate post-operative regional chemotherapy (Pahlman, 1995).

Much effort has also been directed at enhancing the activity of 5-FU by drugs such as leucovorin and levamisole. Recently, the potential of the interferons has been recognized in this respect. Interferons are a family of multifunctional proteins and components of the host defence against viral and parasitic infections and malignancy (Sen and Lengyel, 1992). In vitro studies have demonstrated that each type of interferon may interact with fluoropyrimidines in a synergistic manner to produce cytotoxicity in a variety of human cancer cell lines (see Grem et al., 1995). In phase II trials in patients with advanced colorectal carcinoma the combination of interferon-\(\alpha\), plus or minus leucovorin, with 5-FU appears to possess higher activity than 5-FU alone (Grem et al., 1991; Pazdur, 1991; Waldler et al., 1991). This increased activity is the result of biochemical modulation of 5-FU metabolism, with both enhancement of the inhibition of thymidylate synthase and alteration of the pharmacokinetics of 5-FU being described.

Accepting the hypothesis that immediate post-operative administration of interferon-\(\alpha\), together with 5-FU, might benefit patients after resection of colorectal carcinoma, it becomes essential to investigate the potential effects of these drugs on early anastomotic healing in the intestine. Loss of wound strength increases the risk for anastomotic dehiscence, which is a most serious surgical complication with concomitant high mortality and morbidity. Previous experiments in our laboratory have shown that perioperative intraperitoneal chemotherapy containing 5-FU severely reduces early anastomotic strength (de Rey van Zuidewijn et al., 1991). In addition, daily intraperitoneal 5-FU alone from the day of operation onwards strongly inhibits anastomotic repair in the rat intestine (Graf et al., 1992; de Waard et al., 1995a). If administration of 5-FU remains limited to the day of operation and the first two post-operative days anastomotic strength is not significantly affected (de Waard et al., 1993). In a recent experiment we have examined the effects of 5-FU plus levamisole or leucovorin on anastomotic healing (de Waard et al., 1995b). Here, we describe our experiments into the effects of a 3 day post-operative course of interferon-\(\alpha\) and interferon-\(\alpha\) plus 5-FU on early healing of intestinal anastomoses in the rat.

Materials and methods

Animals

Altogether, 104 male outbred Wistar/Cpb:WU rats, weighing between 200 and 300 g, were used. They were housed with two animals per cage and had free access to water and standard laboratory chow (diet AM II, Hope farms, Woerden, The Netherlands).

For the measurement of anastomotic strength and hydroxyproline content, 80 animals were randomly divided...
into four groups of 20 animals each: a control group, a 5-FU group, an interferon group and a group receiving 5-FU plus interferon. Within each group, ten rats were killed at 3 and 7 days after operation. Collagen synthesis was measured in similar groups of animals (n = 6 each in each group). These rats were killed 3 days after operation. The study was approved by the Animal Ethics Review Committee of the Faculty of Medicine, University of Nijmegen.

Drug administration

5-FU (Abic, Netanya, Israel) was given intraperitoneally in a dose of 20 mg kg⁻¹ body weight (concentration: 1 mg ml⁻¹ saline). This is the same dose we used before (de Waard et al., 1993, 1995a,b) and represents the highest dose which, in combination with surgery, did not result in a significant mortality. Recombinant rat interferon-α (van der Meide et al., 1986; specific activity 6 × 10⁶ U mg⁻¹ protein) was administered intraperitoneally in a dose of 2 × 10⁶ U kg⁻¹ body weight (concentration: 2 × 10⁻¹ U ml⁻¹ saline). The drugs were given once a day, on the day of operation and the next 2 days. The animals in the control groups received intraperitoneal saline daily.

Operative procedure

After an intraperitoneal injection of sodium pentobarbital, a midline incision was made and 1 cm of both small and large bowel was resected, at 15 cm proximal to the ileocecal junction, and 3 cm proximal to the rectal peritoneal reflection respectively. Continuity was restored microsurgically by the construction of an inverted one-layer seromuscular end-to-end anastomosis with eight interrupted sutures of 8 × 0 monofilament material (Ethicon, Sommerville, USA). The abdomen was closed in two layers with a continuous 3 × 0 silk suture for the fascia and staples for the skin.

Analytical procedures

The rats were killed by an intraperitoneal overdose of sodium pentobarbital. After opening the abdominal wound and identifying the anastomoses, the adhesions were cut as far as possible without injuring the intestine. An intestinal segment with the anastomosis in the middle was removed, at 15 cm proximal to the ileocecal junction and 3 cm proximal to the rectal peritoneal reflection respectively. Continuity was restored microsurgically by the construction of an inverted one-layer seromuscular end-to-end anastomosis with eight interrupted sutures of 8 × 0 monofilament material (Ethicon, Sommerville, USA). The abdomen was closed in two layers with a continuous 3 × 0 silk suture for the fascia and staples for the skin.

\]

Incorporation is expressed on the basis of sample wet weight, DNA (Burton, 1956) content or protein (Smith et al., 1985) content.

Statistical analysis

To correct for the fact that multiple comparisons were made, pairwise comparisons of groups were performed (with a two-tailed Mann–Whitney test) using a level of significance of \( \alpha' = 2a/k \), where \( k \) is the number of pairwise comparisons. For instance, differences between the three experimental groups and the control group (Figures 2–4) were considered significant (\( \alpha' = 0.05 \)) at \( P < \alpha' \), where \( \alpha' = 2 \times 0.05/3 = 0.033 \).

Results

No animals died prematurely during the experimental protocol. Up to 24 h after operation, all rats lost approximately 8% of their body weight. Thereafter, animals regained weight, although clear differences were observed between groups (Figure 1). Weight gain in the 5-FU group was significantly slower than in the control group. Administration of

![Figure 1](https://example.com/figure1.png)  
**Figure 1** Course of body weight. Data represent mean values (n = 10) and, for the control group only, the s.d. (O), control group; (●), interferon-α group; (▲), 5-FU group; (■), 5-FU/interferon-α group. Significant differences (P < 0.033, see Materials and methods) between groups are denoted by # (interferon-α w control group), * (5-FU w control group) and $ (5-FU w 5-FU/interferon-α group).
interferon-α appeared to increase the rate of weight gain over the first post-operative days: mean body weight was significantly higher in the interferon-α group than in the control group from day 3 onwards, and in the 5-FU/interferon-α group than in the 5-FU group from day 5 onwards.

Anastomotic strength may be assessed both from the bursting pressure, which represents its resistance to intraluminal pressure, and from the breaking strength, which reflects its ability to withstand longitudinal forces.

Figure 2 depicts the outcome of all measurements of anastomotic bursting pressure performed at 3 days after operation. At this time the bursting site was always within the anastomotic area. In altogether six (out of 80) anastomoses the bursting pressure could not be measured because of technical problems. Neither 5-FU nor interferon-α administration led to a significant change in bursting pressure. However, the mean bursting pressure of ileal anastomoses in the 5-FU/interferon-α group (44 ± 7 mmHg) was significantly (P = 0.0104) lower than that in the control group (70 ± 20 mmHg). In addition, it was also significantly reduced with respect to the 5-FU group (P = 0.0037) and the interferon-α group (P = 0.0062). In colon, these differences did not reach statistical significance. At 7 days after operation the bursting site was always outside the suture line and therefore the bursting pressures measured (data not shown) did not reflect actual wound strength.

When measuring the breaking strength (Figure 3) the breaking site was invariably located within the wound area. At 3 days after operation no differences were found between groups, but after 7 days the breaking strength of both ileal and colonic anastomoses was significantly lower in the 5-FU/interferon-α group than in the control group. Also, anastomotic breaking strength in the colon was reduced in the interferon-α group.

The hydroxyproline content in 5 mm segments containing the anastomosis was quantitated as a measure of wound collagen levels (Figure 4). No differences between the control group and the experimental groups were observed. The hydroxyproline content increased similarly from 3 to 7 days after operation independent of medication. Likewise, no differences were found for hydroxyproline concentrations. Mean hydroxyproline concentrations were 7.0 ± 1.3 and 9.6 ± 1.8 μg mg⁻¹ dry weight in 3- and 7-day-old ileal anastomoses respectively; corresponding values in colonic

The continuing search for effective adjuvant therapy after resection of colorectal carcinoma has resulted in a growing interest in the efficacy of both immediate post-operative regional chemotherapy (see Pâhlman, 1995) and the combination of 5-FU with interferon-α as the cytostatic drugs of choice (see Grem et al., 1995). The present results indicate that caution should be exerted in the use of interferon-α as an adjunct to 5-FU therapy in the early post-operative period since such treatment might constitute a threat to undisturbed anastomotic healing. The combination of interferon-α and 5-FU, administered intraperitoneally on the day of operation and the first two post-operative days, reduces the development of anastomotic strength during the first week after its construction. Administration of 5-FU alone has no significant deleterious effect on wound strength, but interferon-α in itself significantly lowers strength below control values in 7-day-old colonic anastomoses.

The wound healing process is characterised by massive cell migration and proliferation. Cytostatic drugs are by nature anti-proliferative and may therefore be expected to interfere with wound healing. Indeed, 5-FU administered daily from the day of operation onwards until sacrifice after 7 days severely impairs anastomotic healing in the rat intestine (Graf et al., 1992; de Waard et al., 1995b). In earlier experiments, we tried to mitigate this negative effect by concomitant administration of either interleukin 2 or granulocyte-macrophage colony-stimulating factor, but 5-FU impaired repair was not essentially altered by either cytokine. On the other hand, retinol significantly promoted 5-FU suppressed anastomotic healing (de Waard et al., 1995a). Also, we reported before that the negative effect is limited if 5-FU is given only three times (de Waard et al., 1993, 1995a). Since we expected any additional effect of interferon-α to be observed more easily under the latter conditions, we limited drug administration to the first 3 days.

Discussion

The continuing search for effective adjuvant therapy after resection of colorectal carcinoma has resulted in a growing interest in the efficacy of both immediate post-operative regional chemotherapy (see Pâhlman, 1995) and the combination of 5-FU with interferon-α as the cytostatic drugs of choice (see Grem et al., 1995). The present results indicate that caution should be exerted in the use of interferon-α as an adjunct to 5-FU therapy in the early post-operative period since such treatment might constitute a threat to undisturbed anastomotic healing. The combination of interferon-α and 5-FU, administered intraperitoneally on the day of operation and the first two post-operative days, reduces the development of anastomotic strength during the first week after its construction. Administration of 5-FU alone has no significant deleterious effect on wound strength, but interferon-α in itself significantly lowers strength below control values in 7-day-old colonic anastomoses.

The wound healing process is characterised by massive cell migration and proliferation. Cytostatic drugs are by nature anti-proliferative and may therefore be expected to interfere

Differences between groups are considered significant at P<0.017 (a, significant vs control group) and nearly significant (symbols in brackets) at P<0.033. * significant vs control group. $, significant vs 5-FU group; #, significant vs interferon-α group.
So far, little is clear about the effects of interferonα on wound healing. Interferon-γ, delivered intraperitoneally through an osmotic pump (Granstein et al., 1989) or injected subcutaneously (Miles et al., 1994), has been found to delay skin repair in mice. In the latter study, wound disruption strength was reduced significantly at a dose of 7 x 10⁴ U kg⁻¹ body weight and higher. Two experiments, with opposite results, have been reported on the effects of interferonα/β on cutaneous healing in rodents. Intramuscular injection of interferonα/β or intraperitoneal administration of polyinosinic-polycytidylic acid, a potent inducer of interferon, seemingly enhances repair (Bhartiya et al., 1992), while local subcutaneous injection of interferonα/β throughout the wound actually inhibits repair (Stout et al., 1993). In these studies, evaluation of repair was solely on the basis of macroscopic or histological parameters; functional parameters, like wound strength, were not reported.

The present study is the first effort to investigate the effect of purified interferonα on wound strength. Rat recombinant interferonα was given in a daily dose of 2 x 10⁴ U kg⁻¹ body weight. This dose is more than sufficient to protect rats against a lethal pseudorabies virus (PH van der Meide, personal communication), but is substantially lower than the doses of interferon employed in the studies mentioned above. Still, daily doses of this relatively low dose of interferonα, administered on the first three post-operative days, significantly reduce anastomotic breaking strength in the colon 7 days after operation. The results of treatment with the combination of 5-FU and interferonα are probably of more immediate interest in terms of potential treatment of patients with colorectal cancer. It seems clear that addition of interferonα does not lead to further reduction. Whatever the mechanism(s) responsible, our data clearly indicate that administration of interferonα in the perioperative period may be detrimental to anastomotic repair and that its use in immediate post-operative adjuvant therapy, as a means to enhance 5-FU activity, should be approached with caution.
