Abstract

Objective: Despite published guidelines no unified approach to hormone replacement in congenital adrenal hyperplasia (CAH) exists. We aimed to explore geographical and temporal variations in the treatment with glucocorticoids and mineralocorticoids in CAH.

Design: This retrospective multi-center study, including 31 centers (16 countries), analyzed data from the International-CAH Registry.
Methods: Data were collected from 461 patients aged 0–18 years with classic 21-hydroxylase deficiency (54.9% females) under follow-up between 1982 and 2018. Type, dose and timing of glucocorticoid and mineralocorticoid replacement were analyzed from 4174 patient visits.

Results: The most frequently used glucocorticoid was hydrocortisone (87.6%). Overall, there were significant differences between age groups with regards to daily hydrocortisone-equivalent dose for body surface, with the lowest dose (median with interquartile range) of 12.0 (10.0–14.5) mg/m²/day at age 1–8 years and the highest dose of 14.0 (11.6–17.4) mg/m²/day at age 12–18 years. Glucocorticoid doses decreased after 2010 in patients 0–8 years (P < 0.001) and remained unchanged in patients aged 8–18 years. Fludrocortisone was used in 92% of patients, with relative doses decreasing with age. A wide variation was observed among countries with regards to all aspects of steroid hormone replacement.

Conclusions: Data from the I-CAH Registry suggests international variations in hormone replacement therapy, with a tendency to treatment with high doses in children.

Introduction

Congenital adrenal hyperplasia (CAH) represents a group of autosomal recessive conditions leading to glucocorticoid (GC) deficiency. It is caused by defects in the steroidogenic enzymes involved in cortisol biosynthesis or the electron providing factor P450 oxidoreductase (1, 2, 3, 4). The most common form, 21-hydroxylase deficiency (21OHD), associates significant morbidity and mortality (5, 6, 7). Classic CAH due to 21OHD is characterized by a complex imbalance of adrenal steroids resulting in androgen excess, GC deficiency and, in two-thirds of affected individuals, mineralocorticoid deficiency (8). Currently, it is almost impossible to mimic the complex circadian physiology of adrenal steroid biosynthesis by oral glucocorticoid replacement regimes (9). A challenge of GC treatment in CAH remains meeting the adequate balance between normalization of adrenal androgens, often requiring supraphysiological doses, and avoiding GC over-exposure, to minimize negative long-term health problems (10, 11, 12).

International guidelines aiming to optimize the medical management of CAH exist (13, 14, 15). However, they remain relatively broad and are likely to result in variable clinical practice. Furthermore, given the variability in health care provision between different countries, it is reasonable to anticipate geographical heterogeneity in the medical management of CAH. Thus, it is likely that the approach to hormonal replacement therapy in CAH is not uniform across the globe, which may represent an additional challenge to optimizing management and improving health care delivery. In this study, we used information available through the International-CAH Registry (16) and provided evidence for significant variation in the current practice of glucocorticoids and mineralocorticoid replacement in patients with CAH.

Patients and methods

Study design, setting and participants

We conducted a retrospective international cohort study using data recorded in the I-CAH Registry (www.i-cah.org). The I-CAH Registry is an international database of pseudonymized information on patients with CAH and is approved by the National Research Ethics Service in the United Kingdom as a research database of information collected as part of routine clinical care (16). Following informed consent from patients or guardians, data are deposited within the registry by the endocrinologist supervising their management. All patients diagnosed with 21OHD for whom clinical information was recorded in the I-CAH Registry until December 2018 were included in the study. Data collection was conducted using the I-DSD/CAH data fields included in the basic module (register ID, center, country, year of birth, age on presentation, disorder type, actual diagnosis, sex assigned at birth, current gender) and longitudinal module (date of visit, age, weight, height, body surface area (BSA), cushingoid features, virilization, daily adherence to treatment, glucocorticoid type, glucocorticoid dose, timing of glucocorticoid dose, fludrocortisone dose, fludrocortisone frequency). For children data were collected from each visit for the first
Given at the end of this (4). In 8% of patients, different types of GC were recorded at least 50 patient visits.

Data analysis

Hormone replacement analysis consisted of exploring the type of drug used (for glucocorticoids), total daily dose and dose for BSA, the timing of administrations and distribution of doses throughout the day. BSA was calculated using the Mosteller formula (17). We established the following age subgroups: less than 1 year, 1–8 years, 8–12 years, 12–18 years, 18–30 years and more than 30-year, corresponding to infancy, early childhood, middle childhood, adolescence, young adult stage and adulthood respectively. Temporary variations and changes in treatment trends were explored by separating data before and after 2010, chosen in relation to the guidance published by The Endocrine Society (14).

We expressed GC doses for BSA in hydrocortisone equivalent, using the conversion rate: 20 mg hydrocortisone = 4 mg prednisolone/prednisone = 250 µg dexamethasone = 25 mg cortisone acetate, in relation to the suppressive effect on the growth of different types of synthetic steroids (18, 19). As recommended by The Endocrine Society guidelines (15), the target range for GC replacement in 21OHD was defined as 10–15 mg hydrocortisone/m²/day. Visits reporting intravenous doses of GC during acute deteriorations (five patient visits) were excluded from the analysis.

Statistical analysis

Data were analyzed using descriptive statistics and ANOVA, with appropriate adjustments of statistical tests used in accordance to data normality, tested graphically and by using the Shapiro–Wilk test. Hormone replacement doses between groups were compared by Kruskal–Wallis H, Mann–Whitney U and independent T tests. A P value of <0.05 was considered statistically significant throughout the analysis. Statistical analysis and computation were conducted using SPSS Statistics Software version 26 and GraphPad Prism version 8. In exploring aspects of glucocorticoid administration regimes (daily doses, number and timing of doses), we interpreted data from every patient visit as an independent variable. For the descriptive analysis of different treatment practices in different countries, we only included countries that had recorded at least 50 patient visits.

Results

The initial dataset included 4732 patient visits that took place between 1982 and 2018, of which only 2.6% (6% patients) being classified as non-classic CAH (NCCAH). Moreover, 89.3% visit related to patients younger than 18 years, with adult visits only available from three countries (seven centers). Consequently, we limited our analysis to pediatric visits involving patients with classic 21 hydroxylase deficiency (Supplementary Fig. 1, see section on supplementary materials given at the end of this article). We analyzed 4174 visits recording information on 461 patients (54.9% females) from 16 countries and 31 centers (Supplementary Table 1).

Glucocorticoid treatment

Type of glucocorticoids used

Hydrocortisone was used for GC replacement in 90–100% visits by all countries with one exception: in Brazil cortisol acetate was used in 51.8% visits, hydrocortisone in 27.2%, dexamethasone in 13.2% and prednisolone/prednisone in 6.7%. Prednisone was used in a small number of cases: eight visits corresponding to six patients from Brazil and the United Kingdom. Dexamethasone and prednisolone were used in only 2% of visits in children younger than 12 years, and more frequently in children aged 12–18 years (dexamethasone 27.6% and prednisolone 7.8%). Hydrocortisone was most frequently administered following a three daily doses regimen (85%) (Fig. 1A). In 8% of patients, different types of GC were used over time (Supplementary Table 2).

Glucocorticoid administration regimes

The timing of the GC replacement doses varied widely (Fig. 1B and C). The majority of children following a three daily GC regime administered the first dose between 6:00 and 8:00 h, the second dose between 14:00 and 16:00 h and the third dose between 22:00 and 23:00 h. For children taking four daily doses, the observed trend was for the first dose to be given at 4:00 h, the second dose between 11:00 and 12:00 h, the third dose between 16:00 and 17:00 h and last dose at 21:00 h. Of the patient visits reporting three and four daily GC administrations, a circadian dosing regime was identified in 33.1% and a reverse circadian regime in 12.1% of cases, the remaining patients receiving at least two equal doses throughout the day. There was a significant difference in the administration...
strategy between age groups ($P < 0.001$), our results showing that a circadian regime was more frequently used by children aged 8–12 and 12–18 years (47.4 and 50.5% of patient visits, respectively), in comparison to younger children. We also found an important increase in the use of circadian regimes after 2010 for children older than 1 year of age (Supplementary Table 3).

Glucocorticoid daily doses for different age groups before and after 2010

Daily relative GC doses for BSA (Fig. 2A and Table 1) varied significantly among age groups as shown by the Kruskal–Wallis H test ($P < 0.001$). Specifically, patients younger than 1 year had higher doses than children aged 1–8 years ($P < 0.001$) and 8–12 years ($P = 0.030$), patients aged 1–8 years had smaller doses for BSA compared to all other age groups ($P < 0.001$), while patients aged 12–18 years had the highest doses among all age groups with significant difference compared to the 1–8 years ($P < 0.001$) and 8–12 years ($P = 0.004$) group. Analyzing the clinical practice in relation to the international guidelines (14, 15), we found that overall the recommended upper limit of 15 mg/m$^2$/day was exceeded in 37% of patients younger than 1 year of age, 21% of 1-8 year olds, 28% within the 8–12 years group and 39% of patients in the 12–18 years group. No significant difference in relative GC doses between genders were found, with the exception of patients aged 12–18 years, where females received higher doses than males ($P = 0.002$). The fluctuation of GC doses before and after 2010 was inconsistent among age and gender groups.
Glucocorticoid doses for different age groups, before and after 2010. The doses are expressed as hydrocortisone-equivalent (median (interquartile range)).

Glucocorticoid replacement practice in different countries

This analysis only included the 11 countries that recorded 50 or more patient visits. A comparison of hormone replacement between different countries revealed large variations in types of medication, doses and regimens used. While over 90% of countries/centers used hydrocortisone as the preferred GC to treat children, in Brazil the use of cortisone acetate was reported in 51.8% of patient visits, due to limited availability of hydrocortisone. Of the 33 patients treated with cortisone acetate, four patients received exclusively cortisone acetate (during visits recorded before and after 2010), 12 patients were initially treated with cortisone acetate, which was then changed to hydrocortisone at different ages between 1 month and 10 years (for all patients hydrocortisone was started after 2014). 14 patients were treated with cortisone acetate until 12-16 years of age, then the treatment was changed to dexamethasone; two patients initially received cortisone acetate, followed by prednisolone between 4–14 and 10–15 years, respectively, then dexamethasone. The use of circadian administration regimes varied among countries between 0 and 51.3% of patient visits and that of reverse circadian, between 5.0 and 27.9% (Supplementary Table 6). Exploring replacement doses, there were wide variations between countries, especially for children younger than 8 years of age (Fig. 3, Table 3 and Supplementary Table 7). Observing visits recorded in neonates, we noted different strategies of initiating GC replacement, with six of ten countries using hydrocortisone doses above 7.5 mg/day and some having a large variation in doses as wide as 2–15 mg/day (corresponding to 6.6–71.8 mg/m²/day HC-equivalent) (Supplementary Table 8). While for the majority of neonates GC replacement consisted of hydrocortisone, six neonates were started on cortisone acetate (dose range 3–17.5 mg/day, HC-equivalent range 10.5–58.3 mg/m²/ day), five neonates started on prednisolone (dose range 0.4–1 mg/day, 5–21.1 mg/m²/day HC-equivalent) and one

Steroid replacement in CAH

I Bacila and others

Fludrocortisone replacement

Ninety-two percent of patients were treated with fludrocortisone. The majority of patient visits (60.2%) reported a single daily dose of fludrocortisone, 29.8% two and 4.7% three daily doses; for the remaining visits, fludrocortisone frequency was not specified.

The total daily dose of fludrocortisone ranged between 50 and 200 µg/day for the vast majority of patients of all ages, however, relative fludrocortisone doses varied widely across age subgroups (Fig. 4). We identified an increase in the dose after 2010 for all ages for both total and relative daily doses (Table 4), while no significant differences were detected between gender groups (Supplementary Table 9). Comparing doses of fludrocortisone between countries revealed variations across age groups (Supplementary Table 10).

Fludrocortisone replacement

Discussion

Our study explored global trends of hormone replacement therapy in children with 21OHD, providing the first general overview of the medical management of CAH for a wide range of countries across the world. Previous data on this topic consisted mainly of literature reviews and national cohort studies (20), which made comparisons difficult.

Overall, the types of GC used across different age groups was in line with the recommendation of international guidelines. Hydrocortisone was commonly used in children most likely based on its reduced half-life and risk of adverse effects, especially in relation to growth suppression (19, 21, 22). Of note, cortisone acetate was used in a relatively high number of children and young people in Brazil due to lack of availability of oral hydrocortisone preparations. Nevertheless, in over 90% of patients cortisone acetate was replaced by another GC at a later stage. We noted that in some cases this was done in younger, prepubertal children after 2014, most likely following better access to hydrocortisone preparations. In contrast, for patients who were born and diagnosed before 2000, dexamethasone replaced cortisone acetate after the age of 12 years. While we do not have information regarding the clinical reasoning that led to these changes, we can speculate that the timing is related to the completion of linear growth. Using cortisone acetate in children with 21OHD is in line with international recommendations; however, previous publications described its variable bioactivity in relation to the dependency on 11ß-hydroxysteroid dehydrogenase type 1, suggesting higher variability of therapeutic efficiency (23, 24). We observed a number of children visits reporting the use of dexamethasone and prednisolone. The published guidelines advise against using long-acting GC in children due to the significant growth-suppressive effect, especially in the case of dexamethasone (14, 15). Since the use of dexamethasone was mainly limited to children aged 12–18 years, one might argue that patients in this age group may have completed linear growth and had more significant problems with complying to a three-daily glucocorticoid regime. However, it is important to highlight the impact of the type of GC used on other health outcomes, as hydrocortisone has been also shown to be associated with lower prevalence of metabolic comorbidities and better bone health in CAH in comparison to dexamethasone (20, 25, 26).

The wide variations in the timing of the GC doses may relate to the ongoing debate regarding the optimal GC regimen. The majority of children received three or four daily doses of short acting GC, which resonates with previous research focused on optimizing hydrocortisone replacement. Earlier studies demonstrated the high bioavailability and fast clearance of hydrocortisone, recommending frequent and modest daily administrations to better mimic the physiological cortisol profiles (27). Furthermore, clinical studies in patients with adrenal insufficiency recommended the use of three rather than two daily hydrocortisone doses, based on improved cortisol profiles (28, 29, 30). We identified a rise in the use of circadian administration regimes after 2010, which is likely related to the increasing focus on glucocorticoid regimes following a more physiological...
Steroid replacement in CAH

Daily glucocorticoid doses exceeded the recommended range of 10–15 mg/m²/day in a third of children younger than 1 year and between 12 and 18 years. However, there was a marked reduction in the percentage after 2010 for children younger than 8 years. This may relate to the publication of the international guidelines in 2002 and 2010 (13, 14). The reason for the absence of a similar effect in children aged 8–18 years remains unclear. However, adolescents are known to have reduced compliance, together with an increasing degree of independence and reduced parental supervision (34). In addition, cortisol pharmacokinetics are altered at puberty in children with CAH by the decreased cortisol re-activation, secondary to reduced 11ß-hydroxysteroid dehydrogenase type 1 activity caused by the physiological rise of growth hormone and IGF1 (35, 36).

A broad variation between different countries in the approach to GC replacement therapy was observed. This finding is not entirely unexpected considering previously reported variations in GC regimens for different centers within the United Kingdom (37). In some countries the recommended glucocorticoid dose range for children was exceeded in as many as 75% of patient visits, while other countries recorded doses below 10 mg/m² per day in up to 57% of cases. Overall, infants received very high relative doses of GC reaching above 30 mg HC-equivalent/m² per day. In neonates there were particularly marked differences in clinical practice, with half of the countries using hugely variable dose ranges between 4.2–75 mg/m² per day HC-equivalent. Only one center actively reduced GC doses over the weeks following initiation of treatment in a consistent manner. Importantly, studies analyzing growth in children with simple virilizing CAH and delayed treatment found accelerated growth only after the first 12–18 months of life (38, 39), which appears to be a consequence of androgen insensitivity in infancy (40). In addition, the dose-dependent negative effect of GC on linear growth is known and the suppressive action is more marked during age intervals of high growth velocity, including infancy (41, 42). Moreover, there is increased risk of developing metabolic and cardiovascular comorbidities in CAH (43), associated with chronic GC overexposure (44). Although such comorbidities are only becoming fully apparent in adulthood, there is increasing evidence of the onset during childhood (45). These points emphasize the importance of treatment with the lowest possible dose of glucocorticoids by actively reducing cumulative GC doses from a young age starting in infants and young children.

The large majority of fludrocortisone doses in children were within the recommended range of 50–200 μg/day (15). However, high relative doses were used in younger individuals, with doses up to 800 μg/m² per day and 600 μg/m² per day in the under 1 year old and 1–8 years old group, respectively. This trend was consistent across different countries. We could not assess the practice in relation to the dosing strategies used and in the absence of information regarding clinical and biochemical standards of control it is not possible to estimate overtreatment. While there is evidence of renal resistance to mineralocorticoids in infants (46, 47), it was also shown that fludrocortisone treatment is associated with hypertension in children with CAH (48) and there is a correlation between blood pressure and fludrocortisone dose in infants (49). Thus, our findings indicate that the use of absolute doses may lead to overtreatment with fludrocortisone, suggesting a potential benefit to using relative doses of fludrocortisone at least in young children to fine-tune mineralocorticoid replacement.

The aim of this study was to provide an overview on the current practice of hormone replacement therapy in patients with CAH and we focused mainly on the types of medication used, doses and timing of administration. Thus, we acknowledge the absence of clinical and biochemical data as a weakness of the study and identify the need in the future for more in-depth analysis, including such information, in order to increase the clinical relevance of these findings. Another limitation related to data collection, consisting of the overall modest number of countries providing information on patients with CAH by using the I-CAH Registry, as a limited amount of data was available outside of Europe and South America. Moreover, the small number of adult patient visits recorded led to their exclusion from the analysis. However, the I-CAH registry allowed for analysis of a very large dataset in a rare condition, highlighting the value of real-world data and the benefit of using an international registry as a platform for exploring global clinical practice to address questions relevant to improving patient management.
Overall, our results suggest that hormone replacement therapy in children and young persons with classic 21OHD varies widely across different age groups and different countries. It appears that some of these discrepancies relate to physicians’ preference rather than only to physiological difference between individuals. To understand these differences in clinical practice further evidence exploring the interdependency of different management strategies including CAH monitoring methods is urgently warranted. In addition, future research should explore if different clinical practices are associated with differences in long-term outcome in CAH.

Supplementary materials

This is linked to the online version of the paper at https://doi.org/10.1530/EJE-20-1249.

Declaration of interest

R J M Ross is a Director of Diurnal Ltd. Hedi L Claahsen-van der Grinten and Jeremy W Tomlinson are on the editorial board of EJE. They were not involved in the review or editorial process for this paper, on which they are listed as an author.

Funding

This project has received support from the I-CAH Registry project that receives unrestricted education grants from Diurnal Ltd and Neocronne Biosciences. The initial development of the Registry was supported by the Medical Research Council (G1100236), the Seventh European Union Framework Program (201444) and the European Society for Paediatric Endocrinology Research Unit. S R A is supported by the Gardiner Lectureship at the University of Glasgow. N P K is supported by the German Research Foundation (KR3363/3-1).

Data availability

The datasets generated or analyzed during the current study are not available publicly but available to access through a data sharing agreement at https://idsorg.files.wordpress.com/2020/05/i-dsd-i-cah-data-sharing-agreement.docx.

Author contribution statement

Nils P Krone, Irina Bacila, Jillian Bryce, Salma Ali, and S Faisal Ahmed conceptualized and designed the study, designed the data collection instruments, coordinated and supervised data collection, performed the initial analyses, drafted the initial manuscript, and approved the final manuscript as submitted. Irina Bacila and Nicole Freeman undertook the statistical analyses. All authors contributed to data acquisition, revision of the manuscript and have read and approved the final report. All authors take public responsibility and accountability for the results.

Acknowledgements

This work would not be possible without the patients and the parents of the children with CAH whose data have been included in the I-CAH Registry. The author would also like to thank the support of the following reference centers that participate in the European Reference Network for Rare Endocrine Conditions (Endo-ERN): Klinikum Wels-Grieskirchen, Center for Pediatric Endocrinology; Ghent University Hospital; MHAT Sveta Marina, Varna; Aarhus University Hospital; Charité Universitätsmedizin Berlin; Otto-von-Guericke University, Magdeburg; Ludwig-Maximilian-University Munich; Semmelweis University, Budapest; Azienda Ospedaliera Sant’Orsola Malpighi, Bologna; Azienda Ospedaliero Universitaria Città della Salute e della Scienza di Torino; Amsterdam-University Medical Center, Leiden University Medical Center; Radboud University Nijmegen Medical Center; Erasmus Medical Center Rotterdam; University Medical Center Utrecht; University Hospitals Birmingham NHS Foundation Trust; NHS Greater Glasgow and Clyde Board; Barts Health NHS Foundation Trust; Central Manchester University Hospitals NHS Foundation Trust.
