ABSTRACT

We present a dynamical study of the intermediate polar and dwarf nova cataclysmic variable GK Persei (Nova Persei 1901) based on a multisite optical spectroscopy and R-band photometry campaign. The radial velocity curve of the evolved donor star has a semi-amplitude $K_2 = 126.4 \pm 0.9 \text{ km s}^{-1}$ and an orbital period $P = 1.996872 \pm 0.000009 \text{ d}$. We refine the projected rotational velocity of the donor star to $v_{\text{rot}} \sin i = 52 \pm 2 \text{ km s}^{-1}$ that, together with $K_2$, provides a donor star to white dwarf mass ratio $q = M_2/M_1 = 0.38 \pm 0.03$. We also determine the orbital inclination of the system by modelling the phase-folded ellipsoidal light curve and obtain $i = 67^\circ \pm 5^\circ$. The resulting dynamical masses are $M_1 = 1.03^{+0.16}_{-0.11} \text{ M}_\odot$, and $M_2 = 0.39^{+0.07}_{-0.06} \text{ M}_\odot$ at 68 per cent confidence level. The white dwarf dynamical mass is compared with estimates obtained by modelling the decline light curve of the 1901 nova event and X-ray spectroscopy. The best matching mass estimates come from the nova light curve models and an X-ray data analysis that uses the ratio between the Alfvén radius in quiescence and during dwarf nova outburst.

Key words: accretion, accretion discs – binaries: close – stars: individual: GK Persei (Nova Persei 1901) – novae, cataclysmic variables.

1 INTRODUCTION

Cataclysmic variables (CVs) are binary systems where a non-degenerate star fills its Roche lobe and transfers matter towards an accreting white dwarf (WD; Kraft 1964; see Warner 1995 and references therein). For a weakly magnetic WD, the mass from the donor star is accreted on to the surface via an accretion disc. In magnetic CVs, however, the magnetic field is strong enough to dominate at least part of the accretion flow. Polars are the most extreme magnetic CVs: the strong WD magnetic field ($B \gtrsim 10^7 \text{ G}$) prevents the formation of an accretion disc and forces the transferred material to follow the field lines on to one or both poles of the WD (Chamaguam & Wagner 1977; see Cropper 1990 for a review). In contrast, in intermediate polars (IPs) the magnetic field is only able to take control over the transferred plasma in close proximity to the WD (Patterson 1994). In these systems, the accretion disc is truncated at a certain radius from the WD and the disc accretion flow is funnelled from there to its magnetic poles along the field lines. A remarkable difference between both types of magnetic CV is the degree of synchronization of the WD spin with the orbit: in IPs the spin period is usually significantly shorter than the orbital period, while both periods are nearly equal for most polars (see e.g. Norton, Wynn & Somerscales 2004).
GK Persei (GK Per) was discovered as a nova on 1901 February 22 by Scottish amateur astronomer Thomas David Anderson (Williams 1901). It peaked at a visual apparent magnitude of 0.2 mag. After years of irregular fluctuations in brightness with amplitudes up to 1.5 mag and several dozens of days duration, in 1948 it reached a quiescence state ($m_V \approx 13$ mag) and started to show 1–3 mag dwarf nova outbursts that typically last 50 d and recur about every 3 yr (Hudec 1981; Bianchini, Sabadin & Hamzaoglu 1982; Sabadin & Bianchini 1983; Simon 2002).

Crampton, Cowley & Fisher (1986) reported a binary orbital period of nearly 2 d and Watson, King & Osborne (1985) found a WD spin period of 351 s in the modulation of the hard X-ray emission, thus confirming the IP nature of GK Per. The spin period also modulates the $U$-band flux (Patterson 1991) and the equivalent width of the emission lines at optical wavelengths (Garlick et al. 1994; Reinsch 1994). J-band circular polarization of GK Per in quiescence is consistent with a null detection (Stockman et al. 1992).

However, the intensity of the WD magnetic field is estimated at $B \sim 10^7$ G from X-ray spectral modellings (Wada et al. 2018).

The geometrical, kinematic, and physical properties of the nova shell in GK Per and its interaction with its surroundings have been studied in detail at different frequencies (Seaquist et al. 1989; Scott, Rawlings & Evans 1994; Anupama & Kannthara 2005; Liimet et al. 2012, and references therein). In particular, far-infrared observations showed that the nova shell is embedded in an ancient, possibly bipolar planetary nebula centred on the binary and extending $\approx 17$ arcmin to the north-west and south-east (Dougherty et al. 1996). At the time of its discovery, this nebula was interpreted as being the remnant of the binary common envelope phase (Bode et al. 1987). However, ejecta presumably from the WD progenitor star expelled during a second asymptotic giant branch phase (and thus a second common envelope event), triggered by a period of high mass transfer rate from the donor star ($> 3 \times 10^{-7}$ $M_\odot$ yr$^{-1} = 1.9 \times 10^{10}$ g s$^{-1}$), were proposed as a more likely origin for the nebula (Dougherty et al. 1996).

Several spectroscopic classifications of the donor star in GK Per have been reported by different authors: K2 V–IVp (Kraft 1964; Gallagher & Oinas 1974), K0 III–IV (Crampton et al. 1986), K2–3 V (Reinsch 1994), and K1 IV (Morales-Rueda et al. 2002, hereafter MR02). MR02 presented a radial velocity study of the donor star building on similar work by Kraft (1964), Crampton et al. (1986), and Reinsch (1994) that provided an orbital period $P = 1.9968 \pm 0.0008$ d, a radial velocity semi-amplitude $K_2 = 120.5 \pm 0.7$ km s$^{-1}$, and a systemic velocity $V = 40.8 \pm 0.7$ km s$^{-1}$.

MR02 also reported an estimate of the projected rotational velocity of the donor star on the line of sight of the observer ($v_{\text{rot}} \sin i = 61.5 \pm 11.8$ km s$^{-1}$) and a donor-to-WD mass ratio $q = 0.55 \pm 0.21$. In obtaining these values they used optical spectra with $\approx 120$ km s$^{-1}$ full width at half-maximum (FWHM) resolution. Harrison & Hamilton (2015) obtained $v_{\text{rot}} \sin i = 55 \pm 10$ km s$^{-1}$ from near-infrared spectra with $\approx 12$ km s$^{-1}$ FWHM spectral resolution.

Precise dynamical masses of the two stars in GK Per have never been determined because the orbital inclination has remained largely unconstrained. The absence of eclipses in the light curves at optical wavelengths suggested an inclination $i < 73^\circ$ (Reinsch 1994), which translates to lower limits on the masses of the WD and the donor star of $M_1 > 0.87 \pm 0.24$ $M_\odot$ and $M_2 > 0.48 \pm 0.32$ $M_\odot$, respectively (MR02). WD masses of $M_1 = 1.15 \pm 0.05$ $M_\odot$ and $M_2 = 1.22 \pm 0.10$ $M_\odot$ have been derived from modelling of the nova light curve by Hachisu & Kato (2007) and Shara et al. (2018), respectively. In addition, estimates of the WD mass ranging from 0.52$^{+0.34}_{-0.16}$ to $1.24 \pm 0.10$ $M_\odot$ have been obtained through modelling of X-ray spectra (see Section 4 for details).

In this work, we present the first dynamical study of GK Per that yields reliable masses for the WD and the donor star. The paper is structured as follows. In Section 2, we describe the time-resolved optical photometry and spectroscopy observations and the data reduction. From the analysis of the absorption lines of the donor star we obtain its radial velocity curve (Section 3.1), constrain its spectral type (Section 3.2), and determine its rotational broadening (Section 3.3). In Section 3.4, we present the modelling of the $R$-band light curve, which provides the orbital inclination for the first time. The stellar dynamical masses are then obtained using the measured quantities. These are discussed in Section 4, where we also compare the WD dynamical mass with the available estimates from X-ray spectral fitting and modelling of the nova light curve. Finally, we draw our conclusions in Section 5.

### 2 OBSERVATIONS AND DATA REDUCTION

The 1.9968-d orbital period of GK Per makes a given orbital phase occur 4.6 min earlier every next orbital cycle. In addition, during a typical 10-h observing night only 20 per cent of the orbit can be covered. Thus, the fact that the orbital period is close to an integer number of days precludes ground-based observers at a single location from achieving entire photometric coverage of the orbit in contemporaneous nights. This makes the light curve strongly susceptible to aperiodic night-to-night accretion variability. To overcome this difficulty and thus obtain the full ellipsoidal modulation produced by the donor star, we performed multisite photometry between 2017 December and 2018 January. We also took multisite spectroscopy during 2017–2019 to improve the light-curve modelling and obtain a full dynamical determination of the system parameters.

In this section, we describe all the collected data sets. Tables 1 and 2 summarize the spectroscopic and photometric observations, respectively. Note that we have adopted orbital phase 0 as the moment of inferior conjunction of the donor star.
Table 2. Log of the time-resolved R-band photometry.

2.1 Spectroscopy

The optical spectroscopy data of GK Per were obtained in 2017–2019 using four telescopes. We planned the observations in order to cover the orbital phases that better define the radial velocity curve (0.25 and 0.75) and $v_{\text{rot}}\sin i$. The spectral resolution of all our data sets was slit limited. Only the seeing of the 2019 September 7 WHT data (0.7–0.8 arcsec) was slightly less than the slit width (0.8 arcsec), but this was checked to have a negligible influence on the results. Except where indicated, in each observing run we observed the spectral templates HD 20165 and HR 2556, which are classified as K1 V (Koen et al. 2010) and K0 III–IV (Luck 2015) stars and have low intrinsic radial velocities of $-16.92 \pm 0.19$ km s$^{-1}$ and $27.68 \pm 0.17$ km s$^{-1}$, respectively (Gaia Collaboration et al. 2018). Their rotational broadenings are also small: 1.6 km s$^{-1}$ for HD 20165 (Brewer et al. 2016) and 4.3 km s$^{-1}$ for HR 2556 (Luck 2015).

2.1.1 Himalayan Chandra Telescope

The first data set was taken with the 2-m Himalayan Chandra Telescope (HCT) located in the Indian Astronomical Observatory, Saraswati Mount, India. The Hanle Faint Object Spectrograph Camera (HFOSC) was used with grism #8 and a 0.77-arcsec slit width. This instrumental configuration provided spectra in the wavelength range 5120–9310 Å with a dispersion of 1.27 Å pixel$^{-1}$ and a FWHM spectral resolution of 5.6 Å (equivalent to $\sim 270$ km s$^{-1}$ at 6300 Å). We took 20, 24, and 21 spectra using exposure times between 900 and 1200 s on the nights of 2017 December 6, 7, and 8, respectively. FeNe calibration arc lamps were taken often. According to the ephemeris (Section 3.1), these observations covered time intervals near the quadrature of the orbit. The seeing measured from the spectral traces was 1.7–3.6 arcsec during the first night, 1.7–3.2 arcsec on the second night, and 1.7–2.6 arcsec on the last night.

2.1.2 Nordic Optical Telescope

We took a second data set with the 2.56-m Nordic Optical Telescope (NOT) sited in the Observatorio del Roque de los Muchachos on La Palma, Spain. We used the Alhambra Faint Object Spectrograph and Camera (ALFOSC) with grism #8 and a 0.5-arcsec slit width. This set-up yields a wavelength coverage 5680–8580 Å, a dispersion of 1.41 Å pixel$^{-1}$, and a FWHM spectral resolution of 3.5 Å (equivalent to $\sim 170$ km s$^{-1}$ at 6300 Å). These observations were conducted on the nights of 2017 December 8, 9, and 10, when we obtained 30, 21, and 16 spectra, respectively. The exposure time varied between 600 and 900 s. Spectra of HeNe-ThAr calibration arc lamps were taken after each target exposure. This data set covered orbital phase ranges around 0 and 0.5. The seeing was 1.1–2.1, 1.0–1.2, and 0.9–1.5 arcsec on the first, second, and third night, respectively.

2.1.3 William Herschel Telescope

In order to obtain further radial velocities and to measure the rotational broadening of the absorption lines of the donor star, we used the Intermediate-dispersion Spectrograph and Imaging System (ISIS) attached to the 4.2-m William Herschel Telescope (WHT), also located in the Observatorio del Roque de los Muchachos. We took a total of 24 optical spectra during 7 nights between 2018 December 1 and 2019 September 13 using the R600R and the R1200R gratings with different slit widths and central wavelengths (see Table 1). The FWHM spectral resolutions at 6300 Å were $\leq 61$ and $\leq 36$ km s$^{-1}$ for the R600R and the R1200R gratings, respectively. CuNe+CuAr arc lamp spectra were taken just after each target spectrum for wavelength calibration. The spectral templates were only observed with the R1200R grating. In chronological order, the seeing of the WHT spectra was 1.0–1.2, 0.9–1.1, $\sim 0.8$, 0.7–0.8, 3.8–3.9, 1.1–1.3, and 1.3–1.4 arcsec.

2.1.4 Xinglong 2.16-m Telescope

Four spectra close to orbital phase 0.75 were taken with the 2.16-m telescope at the Xinglong Observatory, China, on 2019 November 14. We used the Beijing-Faint Object Spectrograph and Camera (BFOSC) with the G8 grating and a 1.1-arcsec slit width. The spectral range covered was 6000–7550 Å with a dispersion of 1.09 Å pixel$^{-1}$ and a FWHM spectral resolution of 4.8 Å (equivalent to $\leq 228$ km s$^{-1}$ at 6300 Å). We took a spectrum of a FeAr+Ne arc lamp after each target exposure for wavelength calibration. The seeing varied between 3.0 and 4.0 arcsec.

2.2 Photometry

Time-resolved R-band photometry was obtained with four telescopes at different geographical longitudes to achieve a good sampling of almost the entire binary orbit. These photometric data were obtained in the period 2017 December–2018 February. Some of the nights were either close in time (< 1 d) or simultaneous with the NOT and HCT spectroscopy. We used the simultaneous photometry and...
spectroscopy observations to correct for night-to-night variability in the light curve caused by accretion (Section 3.4.1). The observing log is presented in Table 2.

2.2.1 J. C. Bhattacharya Telescope
We obtained time-resolved R-band photometry of GK Per during four nights (2017 December 7–10) using the 1.3-m J. C. Bhattacharya Telescope (JCBT) in the Vainu Bappu Observatory on the Javadi hills of Tamilnadu, India. This photometry is in part simultaneous with some NOT and HCT spectroscopic data sets (Sections 2.1.1 and 2.1.2).

We imaged the GK Per field with the Peltier-cooled Princeton Instruments ProEM CCD camera, an array of 1024 × 1024 13-μm² pixels. This delivers a usable field of view (FOV) of 4.3 × 4.3 arcmin² and a pixel size on the sky of 0.26 arcsec. The full-frame, high-gain (5 MHz frequency) readout mode yielded 1.19 e⁻ ADU⁻¹ and a readout noise of 13 e⁻. We used the Bessel R filter and fixed the exposure time at 600 s.

2.2.2 0.4-m University of Athens Observatory
We used the University of Athens Observatory (UOAO), Greece, a 0.4-m robotic and remotely controlled telescope (Gazeas 2016) to obtain time-resolved R-band photometry of the target on five nights in 2017 December and a further five in 2018 January. Part of the photometry (2017 December 8–10) is simultaneous with some HCT and NOT spectroscopic data sets (Sections 2.1.1 and 2.1.2).

We observed GK Per with the Santa Barbara Instrument Group (SBIG) ST10 CCD camera, an array of 2184 × 1472 6.8-μm² pixels, binned at 2 × 2. The FOV was increased to 17 × 26 arcmin² with the use of an f/6.3 focal reducer, resulting in a plate size of 1.39 arcsec pixel⁻¹. The CCD gain is 1.32 e⁻ ADU⁻¹ and the readout noise 8.8 e⁻. We used the Johnson–Cousins R filter and an exposure time of 60 s.

2.2.3 0.3-m Sutter Creek Observatory
The 0.3-m SC30 telescope located at the Sutter Creek Observatory in California, USA, also provided time-resolved R-band photometry of GK Per on the nights of 2018 January 21 and 28. The observations were carried out with the unbinned 1024 × 1024 CCD array of 24-μm pixels. The images cover a 28 × 28 arcmin² FOV with a plate scale of 1.65 arcsec pixel⁻¹. The CCD readout has a gain of 0.69 e⁻ ADU⁻¹ and a readout noise of 2.81 e⁻. We used the Johnson–Cousins R filter and the exposure time was fixed at 60 s.

2.2.4 0.43-m Sierra Remote Observatories
The 0.43-m f/6.8 Corrected Dall–Kirkham (CDK) telescope at the Sierra Remote Observatories in California, USA, provided further time-resolved R-band photometry of GK Per on 2018 January 25–30 and 2018 February 1–3. The target field was imaged on the 2 × 2 binned 2004 × 1336 CCD array of 18-μm² pixels of the SBIG STXL-11002 camera. This provided a FOV of 42 × 29 arcmin² and a plate scale of 1.26 arcsec pixel⁻¹. The readout gain was 1.74 e⁻ ADU⁻¹ and the readout noise 15 e⁻. We used the Johnson–Cousins R filter with an exposure time of 60 s.

2.2.5 TESS photometry
The Transiting Exoplanet Survey Satellite (TESS) is a space-based optical telescope launched in 2018 to perform an all-sky survey for transiting exoplanets (Ricker et al. 2015). The telescope consists of four cameras, each with a FOV of 24° × 24°. This results in a combined telescope FOV of 24° × 96°. The size of each camera is 4096 × 4096 pixels and the plate scale is 21 arcsec pixel⁻¹. 90 per cent of the flux of a star is contained within a 4 × 4 pixels (1.4 × 1.4 arcmin²) region around its centroid (Ricker et al. 2015). TESS observations are performed in a single photometric band that covers a broad wavelength range from about 6000 to 11000 Å.

The satellite observed GK Per (TESS Input Catalog, TIC 431762266) on 2019 November 3–12 and 15–27 (sector 18). The full-frame images of this sector were taken with a cadence of 30 min by combining nine hundred 2-s exposures.

2.3 Data reduction
All the spectra were reduced, wavelength calibrated, and extracted following standard techniques implemented in IRAF and PAMELA (Marsh 1989, available in the STARLINK distribution). For the NOT and TESS data the pixel-to-wavelength scale was determined with six-term polynomial fits to 33 and 35 arc lines, respectively. For the WHT and Xinglong telescopes we performed third-order spline fits to 16/23 (R600R/R1200R gratings) and 17 arc lines, respectively. The rms scatter of the fits was <0.05 Å for all data sets. We used the [O I] 6300.304 Å sky emission line to look for wavelength zero-point deviations and found they were smaller than the rms scatter of the fitted wavelength calibration, except for the HCT data for which they reach ≃10 km s⁻¹. Hence, we only corrected for these offsets in that case.

The extracted spectra were imported into MOLLY in order to do the analysis described in the next sections and corrected for the Earth motion to have them in the heliocentric rest frame. Times are expressed in Heliocentric Julian Day (UTC). Finally, they were normalized using a seventh-order polynomial fit to the continuum after masking the strong emission lines.

The R-band images were de-biased and flat-fielded using the standard CCD data processing workflow within IRAF. Differential photometry with variable aperture was performed with the HiPERCAM PIPELINE. For this purpose, we used the field stars GK Per-12 (r ≃ 13.4 mag) and GK Per-10 (r ≃ 14.4 mag) labelled in Henden & Honeycutt (1995) and Henden & Honeycutt (1997) as the comparison and check star, respectively.

We obtained the TESS light curve from the 30-min full-frame images using the TESSERACT package (Rojas et al., in preparation) that performs aperture photometry via TESSCAT (Brasseur et al. 2019) and LIGHTCURVE (Lightkurve Collaboration et al. 2018). Visual inspection of the GK Per field revealed some contaminating stars given the limited angular resolution of the TESS images. Using the ALADIN Sky Atlas and the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) Data Release 1 (Chambers et al. 2016), we checked that the six brightest objects in the 4 × 4 pixels

region around GK Per have $r = 14.7–17.8$ mag, fainter than GK Per ($r \approx 12.7$ mag) and non-variable. Hence, these contaminating stars only add a constant veiling to the GK Per light curve. We used an on-target photometric aperture of 1 pixel in order to minimize this contamination. A larger circular aperture was checked to result in a significant decrease of the light-curve amplitude.

3 ANALYSIS AND RESULTS

All uncertainties presented in this and the next sections are quoted at 68 per cent confidence unless otherwise stated.

3.1 Radial velocity curve of the donor star

We measured the radial velocities of the donor absorption lines by cross-correlating each GK Per spectrum with the spectrum of the K1 V HD 20165 template star in the spectral range 6050–6538 Å, after masking the diffuse interstellar band at $\approx 6280$ Å. Prior to this, the template spectrum was corrected for its systemic velocity and for any wavelength zero-point offset by removing the velocity measured by Gaussian fitting the core of the Hα absorption line. Also, all the spectra were rebinned on to a common constant velocity scale. We proceeded in the same way with the K0 III–IV HR 2556 template, which resulted in very similar values of the radial velocities. To account for all uncertainties, the rms of the wavelength calibration was added linearly to the statistical uncertainty of each radial velocity measurement. Since there is no evidence for irradiation of the donor star (see Section 3.3), we performed least-squares sinusoidal fits to the radial velocities, $V(t)$, of the form

$$V(t) = \gamma + K_2 \sin \left( \frac{2\pi}{P} (t - T_0) \right),$$

where $\gamma$ is the heliocentric systemic velocity, $K_2$ the radial velocity semi-amplitude of the donor star, $P$ the orbital period, and $T_0$ the time of closest approach of the donor star to the observer. Fig. 1 shows the radial velocity curve and the best fit. In our preliminary fits, the HCT/HFOSC radial velocities showed a large scatter that the rest of data did not at similar orbital phases, with a deviation of up to 45σ from the initial best fit. We could not identify the reason for this and we excluded these data from the fitting process. In addition, one NOT/ALFOSC radial velocity point was discarded since its deviation was larger than 7σ. After rejecting these deviant points, the $\chi^2$/dof relative to the number of degrees of freedom (dof), $\chi^2$/dof, was $\approx 1.6$ for both templates. We followed by rescaling the radial velocity uncertainties by a factor of $\approx 1.26$ so that the $\chi^2$/dof of the fit was 1.0. The best-fitting parameters for each template are listed in Table 3.

We obtained an orbital period that agrees within 1σ of the value $P = 1.9968 \pm 0.0008$ d reported in MR02. Our $K_2$ determination agrees within 1σ of the value $K_2 = 124 \pm 2$ km s$^{-1}$ reported by Crampton et al. (1986). Their coverage of the radial velocity curve only showed small gaps around orbital phases 0.0, 0.35, 0.45, and 0.9, and they achieved a good sampling of the orbit quadratures.7 On the other hand, our $K_2$ is only consistent with $K_2 = 120.5 \pm 0.7$ km s$^{-1}$ obtained by MR02 at the 4σ level. They cover the orbital phases 0.0–0.3 and 0.5–0.8. However, their radial velocity curve displays a significant number of departing points at phases 0.25–0.30, which probably acted to lower the amplitude of their best sine fit (see fig. 3 in their paper). These authors also obtained a value of $K_2 = 129 \pm 2.7$ km s$^{-1}$ (consistent with ours at the 1σ level) by combining the radial

7Note that Crampton et al. (1986) defined $T_0$ as the time of maximum radial velocity of the donor star and here in Section 3.2 we provide their orbital phase coverage according to our $T_0$ convention.
velocities measured by Kraft (1964), Crampton et al. (1986), and Reinsch (1994). Finally, Crampton et al. (1986) and MR02 obtained a systemic velocity of 28 ± 1 and 40.8 ± 0.7 km s⁻¹, respectively. Our best-fitting γ ≃ 32 km s⁻¹ lies between those two values, but is much closer to the Crampton et al.’s estimate.

### 3.2 Spectral classification of the donor star

The orbital period–mean density (ρ₂) relation for Roche lobe filling stars (Faulkner, Flannery & Warner 1972) yields ρ₂ (g cm⁻³) ≃ 110 P (h⁻²) = 0.048 cm³ g⁻¹ = 0.034 ρ₂ for the evolved donor star in GK Per. This value is in between those expected for main-sequence and giant stars (e.g. ≃ 1.26 ρ₂ and ≃ 0.00031 ρ₂ for K0 V and K0 III, respectively; Cox 2000). In order to constrain the spectral type of the donor star we used two grids of high-resolution (R(K0 III, respectively; Cox 2000) to every template. We performed this analysis in the optimal subtraction technique as described in Marsh, Robinson & Wood (1994) to every template. We performed this analysis in the range G7–K1 with the canonical value for each spectral type (Pecaut & Mamajek 2013). The second grid (Table 4) contains eight spectra of subgiant stars with log g = 3.0–3.6 dex, which is close to the surface gravity of the donor star in GK Per (Section 4.1). This grid covers effective temperatures from 4800 to 5300 K and its metallicity is also −0.10 < [Fe/H] < 0.10 dex.

We used the WHT/ISIS R1200R spectra taken on 2019 September 12 and 13 that cover the orbital phases 0.5 and 0.96, respectively. We selected these data sets to search for potential phase-dependent changes in the spectral classification due to irradiation of the inner face of the donor star by the WD and/or accretion structures. The templates were downgraded to match the resolution of the GK Per spectra by convolution with Gaussian profiles. Then, we applied the optimal subtraction technique as described in Marsh, Robinson & Wood (1994) to every template. We performed this analysis in the spectral range 6050–6400 Å. We proceeded as follows: we corrected for the radial velocity of each GK Per spectrum to velocity-shift them to the rest frame of the template. Next, we computed a weighted average of the GK Per spectra giving larger weights to those with higher signal-to-noise ratio. We subsequently broadened the photospheric lines of the template spectra by convolution with the Gray’s rotational profile (Gray 1992), probing the vrotsin i space between 1 and 150 km s⁻¹ in steps of 1 km s⁻¹. A robust measurement of vrotsin i will be given in Section 3.3, where we will use templates taken with the same instrumental set-up as the GK Per data. We used a linear limb-darkening coefficient of 0.65, a reasonable choice for a K0–3 IV star (Claret, Diaz-Cordoves & Gimenez 1995). Note that similar results are obtained for values of 0.5 or 0.8. The broadened versions of each template spectrum were multiplied by a factor f between 0 and 1 and then subtracted from the weighted-average spectrum of GK Per. This factor represents the fractional contribution of the donor star to the total flux in the wavelength range of the analysis. Finally, we searched for the values of vrotsin i and f that minimized the χ² between the residual of the subtraction and a smoothed version of itself obtained by convolution with a 15-Å FWHM Gaussian. In doing so, we compared the results of using different FWHMs (between 15 and 40 Å) for the smoothing Gaussian. The results were found to be the same within the uncertainties. The minimum χ²/dof for each template is presented in Tables 4 and 5.

The results obtained with the main-sequence templates suggest a spectral type of the donor star in the range G7–K1 with the lowest χ²/dof value found for K1. On the other hand, the χ²/dof values obtained with the grid of subgiant templates provide an effective temperature in the range 4900–5150 K. In this regard, Harrison (2016, see also Harrison & Hamilton 2015) characterized the chemical composition of the donor star in GK Per using near-infrared spectroscopy and synthetic spectral templates with surface gravity log g = 4.0 dex. The effective temperature of their best-fitting template was 5000 K, with an estimated uncertainty of ±110 K, in agreement with our constraint.

Kraft (1964) and Gallagher & Oinas (1974) noticed potential spectral type changes with orbital phase. However, Crampton et al. (1986) found that the average spectra at phases 0.55 and 0.05 (when
we observe the hemisphere of the donor facing and trailing the WD, respectively) were consistent with being identical. Similarly, MR02 found no differences in the spectral type of the donor star between the phase intervals 0.03–0.28 and 0.54–0.82 when applying the optimal subtraction method to their B-band spectra. Our analysis also showed no noticeable changes between phases 0.5 and 0.96. We thus conclude that ultraviolet (UV) and X-ray heating of the donor star is most likely negligible during the quiescence state.

3.3 Binary mass ratio

The donor-to-WD mass ratio ($q = M_2/M_1$) is related to $K_2$ and $v_{\text{rot sin } i}$ through

$$v_{\text{rot sin } i} \simeq 0.49 (1 + q) q^{2/3} K_2 \left[ 0.6 q^{2/3} + \ln(1 + q^{1/3}) \right]^{-1} .$$

This relation is obtained adopting the Eggleton’s approximation for the Roche lobe radius (Eggleton 1983) and under the assumptions that the orbit of the system is circular, the angular momentum vector of both the orbit and the donor star is aligned and that their rotation is synchronized as a result of tidal interactions. Hence, $q$ can be derived from $K_2$ and $v_{\text{rot sin } i}$. The latter is provided by the subtraction of stellar templates described in Section 3.2. Here we apply this technique to all our spectra in the same wavelength range as used in the radial velocity analysis (Section 3.1) with the HD 20165 and HR 2556 spectral templates. The templates were observed with the same instrumental set-up as the target, except for the WHT/ISIS R600R data. In this case, we used the WHT/ISIS R1200R templates smoothed with a Gaussian profile to match the spectral resolution. Fig. 2 displays the normalized, Doppler-shifted average of GK Per before and after the subtraction of the broadened K1 V template.

Evaluation of the uncertainties for $v_{\text{rot sin } i}$ and $f$ was performed by Monte Carlo randomization following the approach in Steeghs & Jonker (2007) and Torres et al. (2020). The optimal subtraction procedure was repeated for 10 000 bootstrapped copies of the GK Per average spectrum. This delivered the distributions of possible values for $v_{\text{rot sin } i}$ and $f$, which are well fitted by Gaussians. Hence, we took their mean and standard deviation as the value and $1\sigma$ uncertainty, respectively (Table 6). The rotational velocities obtained from the NOT, HCT, and Xinglong spectra are overestimated and/or have large uncertainties as a result of the lower spectral resolution ($\simeq$170–270 km s$^{-1}$; see Table 1). The spectral resolution of the WHT/ISIS R600R data is comparable to the $v_{\text{rot sin } i}$ of the system, but the templates were not obtained with the same instrumental set-up. For these reasons, only the measurements of $v_{\text{rot sin } i}$ from the WHT/ISIS R1200R data will be considered.

The observed variability of $v_{\text{rot sin } i}$ with the orbital phase (see Table 6) may be compatible with that expected for a Roche lobe filling donor star (see e.g. Shahbaz, Watson & Dhillon 2014). However, our sampling is insufficient to establish the phase dependence of $v_{\text{rot sin } i}$: only critical orbital phases were covered to estimate its mean value. Taking the averages at phases $\approx$0.0, 0.5, and 0.7 we derive $v_{\text{rot sin } i} = 51 \pm 2$ km s$^{-1}$ and $v_{\text{rot sin } i} = 54 \pm 2$ km s$^{-1}$ for HD 20165 and HR 2556, respectively. Given that the minimum $\chi^2$ value of the optimal subtraction is similar for both templates, we adopt the mean $v_{\text{rot sin } i} = 52 \pm 2$ km s$^{-1}$. Our result is a significant improvement on the previous estimates of 61.5 $\pm$ 11.8 km s$^{-1}$ (MR02) and 55 $\pm$ 10 km s$^{-1}$ (Harrison & Hamilton 2015).

We derived $q$ using equation (2) and $v_{\text{rot sin } i}$ and $K_2$ (Section 3.1). To compute its uncertainty, we followed a Monte Carlo approach: we picked random values of $K_2$ and $v_{\text{rot sin } i}$ from normal distributions defined by the mean and the $1\sigma$ uncertainties of our measurements. We then calculated $q$ for each random set of parameters and repeated this process 10 000 times. The resulting values of $q$ also followed a normal distribution and hence we took the mean and the

**Table 6.** $v_{\text{rot sin } i}$ and $f$ from the optimal subtraction of the HD 20165 (K1 V) and HR 2556 (K0 III–IV, in brackets) template spectra.

$^a$WHT/ISIS R1200R observations that provided robust measurements of $v_{\text{rot sin } i}$. 

---

**Figure 2.** Result of the optimal subtraction technique to measure $v_{\text{rot sin } i}$ and $f$ from the WHT/ISIS spectra taken on 2018 December 1. From bottom to top: spectrum of the K1 V template HD 20165, the average spectrum of GK Per in the rest frame of the donor star, and the residual spectrum after subtraction of the broadened and scaled template. The spectra have been shifted vertically for display purposes. ‘IS’ marks an interstellar absorption band contaminated with telluric absorption.
Figure 3. Construction of the phase-folded R-band light curve of GK Per. Panels (a)–(c) illustrate the steps followed to correct the photometry for night-to-night accretion variability, while panel (d) displays the flux of the GK Per-10 check star relative to the GK Per-12 comparison star. Panel (a) shows the light curve prior to applying any variability correction. Panel (b) displays the light curve after shifting the relative flux of the data points that cover similar orbital phases than the 2017 December 7–10 photometry. The shifts are applied in order to match the mean flux measured during those above nights. Panel (c) shows the result after correcting the flux points at other orbital phases. Each colour in the plot represents a different night. See text for more detail. Two cycles are shown for the sake of clarity.

standard deviation as reliable estimates of its value and uncertainty, respectively. We finally obtain a binary mass ratio:

\[ q = 0.38 \pm 0.03. \]

MR02 reported a highly uncertain \( q = 0.55 \pm 0.21 \) using the same technique with lower resolution B-band spectra. Crampton et al. (1986) estimated \( q = 0.28 \pm 0.04 \) from the quotient of the donor and the H\( \beta \) radial velocity semi-amplitudes. This discrepancy indicates that the H\( \beta \) emission line is indeed not a good tracer of the WD motion, as pointed out by MR02.

3.4 Ellipsoidal light curve and orbital inclination

In this section, we model the R-band light curve of GK Per. We start by detailing the steps followed to obtain an ellipsoidal light curve as free as possible from night-to-night variations due to accretion. Then, we present and discuss the light-curve modelling and provide the binary inclination.

3.4.1 Multi-epoch R-band light curve

We constructed the phase-folded R-band light curve of GK Per using the photometry data described in Section 2.2 (see Table 2) and the ephemeris obtained in Section 3.1. In order to exclude the data points affected by large systematic errors we examined the flux stability of the GK Per-10 check star relative to the GK Per-12 comparison star (see Section 2.3). After some testing, we removed the points with a relative deviation >0.03 mag from the mean. Similarly, points with a statistical uncertainty >0.03 mag were also removed. The bottom panel of Fig. 3 shows the final GK Per-10/GK Per-12 relative flux curve.

The cleaned, phase-folded R-band light curve of GK Per (top panel of Fig. 3) shows clear night-to-night variations likely due to changes in the light contribution of the accretion flow. To correct for these, we took advantage of the partially simultaneous photometry and spectroscopy on 2017 December 7–10. The photometry yielded flux points that cover the orbital phases 0.2–0.5 and 0.65–0.95, respectively.
while the spectra provided a nearly constant $f$ for those nights (see Table 6). The correction consisted of adding or subtracting a constant value to shift the photometry data of all the other nights to match the flux of the above four reference nights. This was accomplished in three steps: first, the light curves that cover the same orbital phases as the reference nights were shifted to the mean reference flux level in the range of coincidence. The resulting light curve is shown in panel (b) of Fig. 3. Second, we applied the flux shifts obtained in the previous step to the light curves that sample different orbital phases during the same nights. By doing this, we are assuming that the variability is negligible for time intervals shorter than 1 d. Finally, the remaining observations were offset to match the mean relative flux of the data points corrected in the significant night-to-night variation (see panels a–c of Fig. 3). For this reason we decided to exclude the 0.0–0.1 orbital phase range from the modelling.

3.4.2 Light-curve modelling

We modelled the $R$-band light curve by fitting synthetic light curves generated with XRBINARY, a code developed by E. L. Robinson. It accounts for the photometric modulation of a binary system composed of a primary star (assumed to be a point source) surrounded by an accretion disc and a corotating Roche lobe (fully) filling donor star. The disc can be non-axisymmetric and vertically extended. The code also allows for an outer disc rim, an inner torus, and disc spots of different brightness. The flux spectrum of the donor star is computed from the stellar atmosphere models of Kurucz (1996) using a non-linear limb-darkening law (Claret 2000b) valid for log $g = 0.0–5.0$ dex. The gravity darkening only depends on the star’s effective temperature and is based on Claret (2000a). The accretion disc is assumed to be optically thick and to emit as a multitemperature blackbody. The disc temperature radial profile is given by $T = K r^{-\beta}$, where $K$ is a normalization constant and $r$ is the distance to the primary star (see the XRBINARY manual for further details). Other accretion structures and the primary star are also assumed to emit as blackbodies. Ray tracing is used to compute the light curve that can be generated for the Johnson–Cousins filters or for square bandpasses (Bayless et al. 2010).

The disc opening angle can be estimated as $\alpha \simeq 2 \arctan[0.038(M/10^{35})^{1/2}]$ (Warner 1995). Following Webbink et al. (1987) and Anupama & Prabhu (1993), we calculated an accretion rate in the disc $M = (1.0–3.8) \times 10^{15} \text{ g s}^{-1}$ for orbital inclinations and WD masses in the ranges 55–72° and 0.8–1.2 $M_\odot$, respectively. On the other hand, Bianchini & Sabbadin (1983) and Wada et al. (2018) presented values very close to $M \simeq 10^{16} \text{ g s}^{-1}$. Considering the accretion rate to be in the range $M \simeq 10^{16–10^{17}} \text{ g s}^{-1}$, we obtain $\alpha \approx 4^\circ–6^\circ$. For the light-curve modelling we adopted the upper limit, although using a flat disc ($\alpha \simeq 0^\circ$) produces the same results. We also assumed a circular disc extending up to the circularization radius $R_c = (1 + q) (b_i/a)^4$, where $b_i$ is the distance from the primary star to the inner Lagrangian point of the system, with $b_i/a = (1.0015 + q^{0.4056})^{-1}$ (Warner 1995).

A detailed description of XRBINARY can be found at http://www.as.utexas.edu/~elr/Robinson/XRbinary.pdf.

Figure 4. Top panel: phase-folded $R$-band light curve of GK Per after correcting for night-to-night accretion variability. Bottom panel: TESS light curve obtained by phase folding six orbital cycles scaled to have the same mean flux. A 0.01 phase binning has been applied to both data sets.

Stellar masses in GK Per

5813

MNRS 507, 5805–5819 (2021)
We fixed the donor star effective temperature \((T_d)\) at 5000 K following the spectroscopic measure by Harrison (2016), which is supported by our analysis in Section 3.2. We did not include either a disc hotspot or donor star-spots given that the \(R\)-band light curve has its two maxima at the same flux level within the errors. In addition, we could not place constrains on the temperature of the disc outer edge or the albedo of the donor star and the disc. However, we checked that these parameters have a negligible impact on the light curve modelling and we fixed them at 2000 K and 0.5, respectively. The free parameters in our model are the orbital inclination \((i)\), the bolometric luminosity of the disc \((L_d)\), the exponent of the disc temperature radial profile \((\beta)\), the disc inner radius \((R_a)\), \(q\), and \(K_i\).

We used the Markov chain Monte Carlo (MCMC) emcee\(^9\) package (Foreman-Mackey et al. 2013) in PYTHON along with wide uniform uninformative priors for \(\beta\) and \(R_a\). The prior for \(L_d\) was flat in log space to allow for an even sampling of the parameter space across orders of magnitude. The absence of eclipses in GK Per (Reinsch 1994) implies \(i \lesssim 73^\circ\) (MR02) and the Chandrasekhar mass limit for a WD imposes \(i \gtrsim 55^\circ\). We used a flat prior for \(\cos i\) and conservatively adopted a 50°–85° range. We adopted Gaussian priors for \(K_i\) and \(q\), with the mean and standard deviation values obtained in Sections 3.1 and 3.3, respectively. We ran the MCMC sampler for 10000 steps with 40 walkers and discarded the first 50 per cent as burn-in. In each iteration, the comparison between the synthetic and the actual \(R\)-band light curves is based on the likelihood function of a continuous distribution, computed after normalizing the synthetic light curve to be at the same flux level as the observed one. After several trials we mostly found flat/wide posteriors for \(R_a\) and \(\beta\), so we were unable to constrain them. Therefore, we decided to marginalize over these two parameters and provide the correlation plot (Fig. 5) for the remaining parameters and the inferred ones \((M_1\) and \(M_2\)), whose posterior distributions are close to normal. Table 7 provides the fixed and the fitted model parameters, with the quoted uncertainties established from the 68th percentiles in the distributions.

The best-fitting model light curve \((\chi^2/d\text{of} = 0.6)\) is presented in the top panel of Fig. 6 as a solid line. It provided a donor star fractional contribution to the \(R\)-band flux \(f = 0.73 \pm 0.02\), in agreement with what we found from the spectroscopy using the KO III–IV template in and (Jonsson et al. 2020). The MCMC analysis yields an orbital inclination of \(i = 67^\circ \pm 5^\circ\). In Fig. 6, we show two synthetic light curves computed using the best-fitting parameters and the above inclination limits of 55° and 73° (dotted and dashed lines, respectively). The 82°–86° binary inclination obtained by Kim, Wheeler & Mineshige (1992) from modelling of the dwarf nova outbursts can be rejected, while the estimate of 66° reported in Bianchini et al. (1982) is in line with our measurement. From our value of the orbital inclination we derive the following binary masses:

\[
M_1 = 1.03^{+0.16}_{-0.11} \text{M}_\odot, \quad M_2 = 0.39^{+0.07}_{-0.06} \text{M}_\odot.
\]

The lack of data points around phase 0 in our \(R\)-band light curve does not allow us to firmly discard disc eclipses. However, the TESS light curve suggests that they are either too shallow to be detected or absent. We have computed \(R\)-band synthetic light curves and have assumed that the eclipse depth is the same in both the TESS and the \(R\) bands. Disc eclipses deep enough to be noticeable in the TESS light curve would then be produced for \(i \gtrsim 71^\circ\). Thus, the binary inclination is most likely \(i \lesssim 71^\circ\), which means that our upper limit on the uncertainty in \(i\) is overestimated by 1°. In turn, this leads to a negligible overestimate of 0.01 \(\text{M}_\odot\) for the lower limit on \(M_1\). Another source of systematic errors in the masses is a potential incorrect determination of the relative contribution of the donor star and the accretion flow to the \(R\)-band flux. Using the optimal subtraction technique (Section 3.3) we determined \(f \approx 0.66–0.70\) or \(f \approx 0.73–0.79\) depending on the template, while the best-fitting light curve model yields \(f = 0.73\). Modifying the phase-folded data to simulate light curves with \(f = 0.65\) and \(f = 0.8\) results in \(i = 66^{+4}_{-5}\) and \(i = 68^{+4}_{-5}\), respectively. These changes in the inclination have an impact on the derived masses lower than the reported statistical uncertainties. Finally, we have also tested the systematic errors associated with the adopted \(T_d\). Fixing the temperature of the donor at either \(T_d = 4700\) K or \(T_d = 5300\) K results in an orbital inclination of \(i = 68^{+4}_{-5}\) and \(i = 66^{+5}_{-5}\), respectively. Thus, even considering these less probable values for \(T_d\), its effect on the dynamical masses is significantly lower than the statistical uncertainties.

4 DISCUSSION

4.1 Binary masses

The mass and radius of the Roche lobe filling donor in GK Per are \(M_2 = 0.39^{+0.07}_{-0.06} \text{M}_\odot\) and \(R_2 = \frac{M_2}{\frac{M_1 + M_2}{2} \sin i} = 2.26 \pm 0.12 \text{R}_\odot\), respectively, which clearly indicate that the donor star is evolved. In fact, we derive \(\log g = 3.31 \pm 0.09\) dex, which differs from \(\log g = 4.0\) dex adopted by Harrison (2016) to measure a donor effective temperature \(T_d = 5000\) K and a metallicity \([\text{Fe/H}] = -0.3\) dex from synthetic template spectra. However, our spectral classification using empirical subgiant templates in the range \(\log g = 3–3.6\) dex provides a very similar temperature of \(\approx 4900–5150\) K. The above value for \(T_d\) is also supported by observations of evolved field stars with \(\log g \approx 3.2–3.4\) dex and metallicities from \(-0.2\) to \(-0.4\) dex that have effective temperatures of \(4900–5100\) K (Alves et al. 2015). On the other hand, if the donor star were a stripped giant with all its properties dependent on the mass of its helium core, we could derive its effective temperature from \(R_2\). Following the equations given in Webbink, Rappaport & Savonije (1983) and King (1988) we obtained a core mass \(0.179 \pm 0.002 \text{M}_\odot\), a luminosity \(2.16 \pm 0.19 \text{L}_\odot\), and \(T_d = 4660 \pm 26\) K. This lower \(T_d\) could be an indication that the donor star in GK Per is not a stripped giant as initially suggested by Watson et al. (1985). This would imply that its initial mass was \(\lesssim 1.4 \text{M}_\odot\) (Ziolkowski & Zdziarski 2020).

Our dynamical study of GK Per has also provided a WD mass \(M_1 = 1.03^{+0.16}_{-0.11} \text{M}_\odot\). Zorotovic, Schreiber & Gänsicke (2011) found an average mass of \(0.83 \pm 0.23 \text{M}_\odot\) from robust measurements in 32 CVs. This value is significantly higher than the mean of \(0.61–0.64 \text{M}_\odot\) established for isolated WDs (Kepler et al. 2016). The WD mass in GK Per is no exception – it is among the 10 more massive ones in Zorotovic et al.’s (2011) sample.

4.2 Comparison with previous WD mass estimates

Hachisu & Kato (2007, see also Hachisu & Kato 2015) fitted the 1901–1919 decay light curve of the nova event. They adopted the model described in Hachisu & Kato (2006) that uses a decay law for the optical flux, \(F_s \propto t^{-\gamma}\), and considers a spherical ejecta whose optical-to-infrared continuum flux is dominated by free–free emission from the optically thin region. They model the different

Figure 5. Correlation diagrams of the probability distributions of the best-fitting parameters from the MCMC modelling of the ellipsoidal light curve. The contours in the 2D plots show the 68, 95, and 99.7 per cent confidence regions. The right-hand panels show the projected 1D distributions of the parameters, where we mark the mean (solid line) and 68 per cent confidence level intervals (dashed lines). $M_1$ and $M_2$ are inferred values from $q$, $K_2$, $P$, and $i$.

Stellar masses in GK Per

stages of the flux decay using a sequence of steady-state solutions and find that the decline rate depends weakly on the chemical composition and is very sensitive to the WD mass. They provided a WD mass (hereafter $M_{\text{nova}}^1$) as a function of the hydrogen content of the ejecta, $X$, as $M_{\text{nova}}^1(X) = 1.15 \pm 0.05 \, M_\odot$. Note that according to Pottasch (1959) the hydrogen content of the nova ejecta in GK Per is $X \approx 0.54$. The WD mass obtained from the nova light curve agrees within 1σ of our dynamical measurement.

More recently, Shara et al. (2018) interpolated the grid of nova models from Yaron et al. (2005) to construct functions for the WD mass and the accretion rate depending on the flux amplitude and the mass-loss time of a given nova. Assuming that the latter is equal to the decline time and fitting these functions to the light curve of Nova Persei 1901 they derived $M_{\text{nova}}^1 = 1.22 \, M_\odot$ with an estimated statistical uncertainty of $\sim 0.1 \, M_\odot$. Our dynamical measurement is also in agreement within 1σ of this value.

Attempts to derive the WD mass from modelling of X-ray data (hereafter $M_X^1$) have been reported by different authors. The simplest X-ray models for IPs assume that the accreted matter falls almost radially on to the WD from infinity. Hence, the temperature of the plasma in the post-shock region, $T_s$, may reflect the depth of the
Table 7. Fixed and fitted parameters of the R-band light-curve modelling. The type of prior for each parameter was: flat for $\beta$ and $R_{\text{wd}}$, flat in log space for $L_{\text{bol}}$, flat in cosine space for $i$, and Gaussian for $K_2$ and $q$ (based on the results presented in Sections 3.1 and 3.3).

The gravitational potential of the WD (Aizu 1973):

$$kT_1 = \frac{3}{8} \frac{GM_1^X}{R_1} \mu m_1 H = 16 \left( \frac{M_1^X}{0.5 M_\odot} \right) \left( \frac{R_1}{10^8 \text{ cm}} \right) \text{ (keV)},$$

(3)

where $R_1$ is the radius of the WD, $\mu$ is the mean molecular weight ($=0.615$ for solar abundance plasma), and $m_1$ is the mass of the hydrogen atom. Given that $R_1$ can be expressed as a function of the WD mass using a mass-radius relation (e.g. Nauenberg 1972), the temperature can be expressed as a function of the WD mass only. The hot post-shock region cools mainly via thermal bremsstrahlung emission in the hard X-ray regime. Hence, the easiest way to estimate the plasma temperature and thus derive the WD mass is to fit the hard X-ray spectra with single-temperature bremsstrahlung models and adopt the best-fitting temperature as the maximum shock temperature.

Landi et al. (2009) fitted the combined 0.2–10 keV *Swift* X-Ray Telescope (XRT) and 20–100 keV *International Gamma-Ray Astrophysics Laboratory* (INTEGRAL)/Imager on Board INTEGRAL Satellite (IBIS) spectrum of GK Per with a blackbody plus bremsstrahlung model for the soft and hard X-ray emission, respectively, taking into account the local and interstellar absorption. The best-fitting bremsstrahlung temperature $kT_1 = 23^{+10.2}_{-5.2}$ keV yields (equation 3) $M_1^X = 0.87^{+0.21}_{-0.12} M_\odot$ (Brunschweiger et al. 2009). Given its large uncertainty this mass estimate agrees within 1σ of our dynamical measurement.

Other authors have considered a multitemperature continuum post-shock region. Suleimanov, Revnivtsev & Ritter (2005) presented a model with temperature and density as functions of the distance to the WD surface under the assumption that matter is accreted from infinity. The latter is a good approximation when the Alfvén radius is more than 10 times larger than the WD radius. They fitted this model to a 3–100 keV outburst spectrum of GK Per obtained by combining the *Rossi X-ray Timing Explorer* (RXTE)/Proportional Counter Array (PCA) and High-Energy X-ray Timing Experiment (HEXTE) data and found a much lower WD mass of $M_1^X = 0.59 \pm 0.05 M_\odot$. Given that $R_1/R_1 < 5$ when GK Per is in outburst and $R_1/R_1 < 10$ during quiescence, Suleimanov et al. (2005) concluded that their value of $M_1^X$ obtained from outburst data underestimated the WD mass by at least 20 per cent. Our dynamical mass measurement allows to establish that their $M_1^X$ actually underestimates the WD mass by 73$^{+40}_{-17}$ per cent. These authors also fitted their models to the 3–20 keV PCA data alone and obtained $M_1^X = 1.24 \pm 0.10 M_\odot$. They showed that the use of the X-ray continuum in the energy range < 20 keV does not provide an accurate estimate of $M_1$ because for WD masses > 0.6 $M_\odot$, the post-shock temperature is > 20 keV. Further, the IP X-ray continuum in that range is affected by interstellar and intrinsic absorption and possibly a reflection component. In this regard, Evans & Hellier (2007) fitted the multitemperature continuum model for the post-shock region by Cropper et al. (1999), which is similar to that in Suleimanov et al. (2005), to a 0.2–12 keV *XMM–"

Figure 6. Top panel: phase-folded R-band light curve and the best-fitting synthetic model (solid black line). The points in grey colour (phases 0.0–0.1) have been masked during the fit. The flux of the accretion disc (not shown) in the model is constant along the whole orbit, while the fractional contribution of the donor star to the relative flux is $f = 0.73 \pm 0.02$. The dashed and dotted lines represent the synthetic light curves for $i = 73^\circ$ and $i = 55^\circ$, respectively. Bottom panel: residuals from the fit.
Newton/European Photon Imaging Camera (EPIC)-pn spectrum of GK Per in outburst. The fit provided $M_{\text{H}}^S = 0.92_{-0.11}^{+0.33} M_\odot$, which agrees with our measurement given the large uncertainties.

The systematic underestimate of the WD mass of GK Per as a function of its accretion state was explored by Brunschwiger et al. (2009). They fitted the Suleimanov et al. (2005) model to both quiescence and outburst 15–200 keV Swift/Burst Alert Telescope (BAT) spectra. For the outburst data they derived a mass $M_\text{H}^S = 0.67–0.74 M_\odot$ lower than the result in quiescence $M_\text{H}^S = 0.90 \pm 0.12 M_\odot$. They suggested a true WD mass of 1.15 $M_\odot$ from fitting the relation between $M_\text{H}^S$ and the accretion rate of the system when the data are taken. This value is in line with our result.

In order to determine a $M_\text{H}^S$ free of this underestimate effect, Suleimanov et al. (2016) proposed a method that obtains $M_\text{H}^S$ and $R_A$ simultaneously from the break frequency of the power spectrum\(^{10}\) and a model with the matter falling from $R_A$, not from infinity. By fitting this refined model to a 20–80 keV Nuclear Spectroscopic Telescope Array (NuSTAR) spectrum of GK Per in outburst they found $M_\text{H}^S = 0.86 \pm 0.02 M_\odot$ and $R_A/R_1 = 2.8 \pm 0.2$. This same method was applied to a 20–80 keV NuSTAR spectrum taken in quiescence (Suleimanov, Doroshenko & Werner 2019) that provided $M_\text{H}^S = 0.79 \pm 0.01 M_\odot$ and $R_A/R_1 = 3.18 \pm 0.17$. These $M_\text{H}^S$ values are consistent within 2$\sigma$ of the dynamical WD mass presented in this work.

Other methods have been explored to derive the WD mass in GK Per using X-ray data. Ezuka & Ishida (1999) fitted the continuum emission of a 0.5–10 keV spectrum of GK Per in outburst combined the Advanced Satellite for Cosmology and Astrophysics (ASCA)/Solid-state Imaging Spectrometer (SIS) and Gas Imaging Spectrometer (GIS) data. Their model consists of single-temperature thermal bremsstrahlung that undergoes multicolour absorption. This included the fluorescent (6.4 keV) and plasma (6.7 and 7.0 keV) components of the Fe Kα emission line. They used the intensity ratios of these lines to measure the ionization temperature and obtained $kT = 7.8_{-2.1}^{+2.8} \text{keV}$. They also derived a relation between this and the corrected temperature of the continuum (see panel b of fig. 4 in Ezuka & Ishida 1999). This yields $M_\text{H}^S = 0.52_{-0.16}^{+0.34} M_\odot$ (90 per cent confidence level). The discrepancy with our $1.03_{-0.11}^{+0.16} M_\odot$ dynamical value shows that the above temperature relation must be improved in order to obtain reliable WD masses. Finally, Wada et al. (2018) derived a $M_\text{H}^S$–$R_A$ relation for a given temperature of the post-shock region by modifying equation (3) to account for the free-fall initial point and the shock height. They fitted a multitemperature optically thin plasma model to the quiescence and outburst NuSTAR spectra analysed in Suleimanov et al. (2016, 2019). From the flux and plasma temperature measured at different accretion states they established that $R_A$ in quiescence is 3.9 times larger than during outburst. By finding the $M_\text{H}^S$ value that satisfies this condition they derived $0.87 \pm 0.08 M_\odot$, which is consistent within $1\sigma$ of our dynamical mass.

5 CONCLUSIONS

We have presented a dynamical study of the IP CV GK Per 120 yr after its nova explosion. We obtained the radial velocity curve of the donor star and refined the orbital period of the system to $1.996872 \pm 0.000009$ d and $K_2$ to $126.4 \pm 0.9 \text{ km s}^{-1}$. From our higher resolution spectroscopy we established a rotational broadening for the donor star absorption lines $v_{\text{rot}} \sin i = 52 \pm 2 \text{ km s}^{-1}$. Partially simultaneous photometry and spectroscopy allowed us to construct a phase-folded R-band light curve as free as possible from night-to-night accretion variability. Modelling of the light curve allowed to establish the binary orbital inclination $i = 67.5 \pm 5^\circ$. We derived the dynamical masses 1.03$^{+0.16}_{-0.11}$ and 0.39$^{+0.07}_{-0.06}$ $M_\odot$ for the WD and the evolved donor star, respectively. Table 8 summarizes the fundamental parameters derived in this work.

The WD in GK Per has one of the highest masses confirmed dynamically for a CV and our value is in agreement with those obtained from modelling of the nova decay light curve. We also compared the WD mass with X-ray modelling estimates. We confirm that the WD mass values derived from the hard X-ray spectra (>20 keV) continuum temperature assuming matter free falling from infinity are significantly underestimated. Models considering gas free falling from a finite distance (Suleimanov et al. 2016, 2019) agree with our measurement within 2$\sigma$. The same degree of agreement is found for the estimates obtained from the intensity ratio of the fluorescent and plasma components of the Kα emission line (Ezuka & Ishida 1999). On the other hand, the WD mass value obtained by Wada et al. (2018) using the quiescence-to-outburst Alfven radius ratio is consistent within 1$\sigma$ of our dynamical measurement.

Our robust dynamical mass for the WD in GK Per has served as a stringent test for the values reported by other authors using indirect methods. However, a more accurate $M_1$ is still needed to further constrain the nova decay light-curve and X-ray spectral modelling techniques. Future multicolour photometry sampling the full binary orbit will likely result in a more precise value of the inclination that could potentially lead to a refined dynamical WD mass.

Finally, our study supports a subgiant donor with an effective temperature of $\approx$5000 K, in line with the values obtained from infrared spectroscopy by Harrison et al. (2013) and Harrison (2016). The stripped giant model failed to explain the observed temperature, which suggests that the initial mass of the donor star was $\lesssim 1.4 M_\odot$.

ACKNOWLEDGEMENTS

We thank the anonymous referee for a careful review of the manuscript and useful comments. MAPT and PR-G acknowledge support from the Spanish State Research Agency (AEI) of the Spanish Ministry of Science, Innovation and Universities (MICIU) and the European Regional Development Fund (FEDER) under grants AYA2017-83216-P and AYA2017-83383-P, respectively. MAPT was also supported by a Ramón y Cajal Fellowship RYC-2015-17854. AR acknowledges the Research Associate Fellowship with order no. 03(1428)/18/EMR-II under Council of Scientific and Industrial Research, India (CSIR). J-R is thankful for support from NSFC.
DATA AVAILABILITY

The NOT and WHT data are available at http://www.not.iac.es/observing/forms.fitsarchive/ and http://casu.ast.cam.ac.uk/casuads-ingarch/query, respectively. They can be searched by observing date and object coordinates. The 0.3-m SC30, 0.43-m CDK, 0.4-m UOAO, and 2.16-m Xinglong data are available from the corresponding staff. The HCT and 1.3-m JCBT data will be made available by GCA and MP on request.
