Received Nov. 12, 1996; revised Jan. 9, 1997; accepted Jan. 13, 1997.

Variability in susceptibility to diseases is a well known phenomenon that has been attributed to genetic and environmental factors. At the level of the immune system, the reactivity of two types of T helper cells (Th1 and Th2 cells) plays an important role in determining disease susceptibility. Inflammatory (autoimmune) diseases are stimulated by cytokines produced by Th1 cells. Th2 cytokines stimulate antibody production (e.g., IgE) and eosinophilia as observed in allergic reactions or during parasitic infections. We describe here that the reactivity in a Th1 or a Th2 disease model significantly differs between individual rats that show group-specific differences in reactivity of the hypothalamic–pituitary–adrenal (HPA) axis, as well as in their behavioral responses to stress.

We used two outbred lines of Wistar rats, apomorphine-susceptible rats that have a relatively hyperreactive HPA axis (APO-SUS) and apomorphine-unsusceptible rats that have a relatively hyporeactive HPA axis (APO-UNSUS). APO-SUS, but not APO-UNSUS, rats generated a vigorous, Th2-dependent IgE response after infection with the nematode Trichinella spiralis. In contrast, APO-UNSUS, but not APO-SUS, rats were susceptible for Th1-mediated experimental autoimmune encephalomyelitis. Investigation of cytokine responses of splenocytes revealed that the ratio of mRNA expression for Th1-derived interferon (IFN)-γ and mRNA expression of Th2-derived interleukin-4 (IL-4) was significantly smaller in APO-SUS than in APO-UNSUS rats.

In conclusion, individual differences in structure and reactivity of the neuroendocrine system co-occur with group-specific differences in susceptibility to inflammatory and infectious diseases.

Key words: experimental autoimmune encephalomyelitis; T cells; hypothalamus–pituitary–adrenal axis; rats; Trichinella spiralis; interferon-γ; interleukin-4
and Sud, 1996). Alterations of the cytokine pattern in vivo can reverse host resistance or susceptibility to disease (Liblau et al., 1995). The production of Th1 and Th2 cytokines can, at least in vitro, be modulated by neuroendocrine mediators (Daynes and Aranéo, 1989; Daynes et al., 1990; Rock et al., 1994). It is not known, however, whether the neuroendocrine system in vivo contributes to the Th1/Th2 balance and to disease susceptibility. However, studies in inbred rats have presented evidence that the neuroendocrine system can contribute to susceptibility to inflammatory autoimmune disease (Macphee et al., 1989; Sternberg et al., 1989a,b). Rats with a blunted reactivity of the HPA axis like Lewis rats are susceptible to EAE and arthritis, whereas Fischer F344 rats are resistant in models of autoimmunity (Macphee et al., 1989; Sternberg et al., 1989a). Moreover, we have evidence that APO-SUS and APO-UNSUS animals differ in EAE susceptibility (Cools et al., 1993).

The aim of the present study was to establish whether the reactivity of the neuroendocrine system of APO-SUS and APO-UNSUS rats is coupled to a group-specific reactivity in two fundamentally different disease models, namely the EAE model for Th1-dependent, autoimmune diseases and the IgE response to infection with the nematode *T. spiralis* for Th2-dependent, infectious diseases.

**MATERIALS AND METHODS**

**Animals.** Male Wistar rats of the APO-SUS and APO-UNSUS lines bred and reared in the Central Animal Laboratory of the University of Nijmegen were used. The selection procedure has been described in detail by Cools et al. (1990). In short, a group of 60 male and 60 female rats of an outbred Wistar population was given s.c. injections of 1.5 mg/kg apomorphine, which induces a stereotypic gnawing behavior. The gnawing score was determined in a modified “Ungerstedt-box,” allowing a quantitative measurement of serum level of IL-4 are not yet available, the expression of IL-4 mRNA as well as of IFN-γ mRNA was determined by quantitative RT-PCR to gain insight into the relative contribution of Th1 or Th2 type responses in APO-SUS and APO-UNSUS rats. At the time point when the above-mentioned supernatants were collected, cells were harvested and RNA was extracted by the use of RNAzol B (Campro Scientific, Veenendaal, The Netherlands). Two micrograms of RNA were reverse transcribed into cDNA using AMV reverse transcriptase and oligo-dT 12-18 oligonucleotide as primer according to the manufacturer’s protocol. Quantitative competition PCR was performed as described by Siegling et al. (1994), and kindly provided us with a competitor plasmid containing primers for β-actin, IFN-γ, and IL-4. Serial dilutions of competitor fragment were complied with fixed amounts of cDNA. The PCR product for the sample cDNA and the competitor differ in size so that the relative intensities of the two products can be compared. For calculations, 1 unit of cDNA signal was defined as the amount that resulted in equal density of competitor and target cDNA at 1 µl of 1:50 dilution of the competitor. The following primer pairs were used: β-actin sense, 5'-CTATGGCAATAAGCCTTAC; antisense, 5'- CTTAGGATGTTGGGTGGC; IFN-γ sense, 5'-CCCTCTCTGGCCGGTACTAG; antisense, 5'-CCCTTCTTCCGTCCCTTAC; IL-4 sense, 5'-ATGCCACCGATTTTGTTAC; antisense, 5'-TTTCTACTGTTTCTAGCGTTGA. These primer pairs gave rise to PCR products for β-actin of 762 bp for sample cDNA and 601 bp for competitor fragment. IFN-γ sample cDNA yields a fragment of 419 bp, whereas the competitor results in a fragment of 319 bp. For IL-4, sample cDNA results in 275 bp and competitor cDNA in 178 bp. cDNA was amplified in a 20 µl reaction volume containing 2 µl of 10X PCR buffer, 0.25 mM each dNTP, 50 ng/ml of the appropriate primer pair, 2 mM MgCl₂, and serial dilutions of competitor fragment. After 5 min denaturation at 94°C, cDNA samples were subjected to cycles of denaturation (15 sec at 94°C), annealing (15 sec at 60°C), and extension (15 sec at 72°C) using the thermal cycler GeneAmp 9600 (Perkin-Elmer). To correct for variations across different preparations, cDNA samples were adjusted to equal input cDNA concentrations based on their β-actin content before determination of cytokine cDNA content. Control PCRs without cDNA were performed in all experiments to exclude contamination.

**RESULTS**

**Susceptibility to experimental autoimmune encephalomyelitis**

APO-SUS and APO-UNSUS rats showed a clear difference in susceptibility to EAE (Fig. 1 and Table 1). APO-SUS rats were less susceptible for EAE. The incidence of disease and the mean cumulative clinical score were lower in APO-SUS animals than in APO-UNSUS animals. In addition, there was a significant difference in the kinetics of disease development. APO-SUS animals showed a significant delay with respect to onset of the disease when compared with APO-UNSUS rats. The first symptoms of disease were observed only at day 12 after inoculation in APO-SUS rats. In contrast, APO-UNSUS rats showed the first symptoms of the disease at day 8 after inoculation, the degree of paralysis increased reaching maximal levels at day 11 after inoculation in these animals; subsequently, disease activity gradually decreased, and complete remission was observed after 18 d. There was no group-specific difference in duration of the disease.

**Response to inoculation with *Trichinella spiralis***

APO-SUS rats developed a higher level of anti-*T. spiralis* IgE than APO-UNSUS rats (Fig. 2). In eight of nine APO-SUS animals, *T. spiralis*-specific antibodies of the IgE subclass could be detected.
Figure 1. Expression of EAE in APO-SUS and APO-UNSUS rats. Male APO-SUS (n = 7) and APO-UNSUS (n = 7) rats were inoculated with MBP in CFA on day 0. Clinical signs of the disease were scored daily on a scale from 1 to 5 as described in Materials and Methods. For statistical analysis of the data, see Table 1.

whereas only two of seven APO-UNSUS rats developed detectable levels of parasite-specific IgE.

There were no group-specific differences in the levels of IgG or IgA specific for T. spiralis (Table 2).

Production and/or mRNA expression of Th1 and Th2 type cytokines

The splenocytes of APO-SUS and APO-UNSUS rats did not show group-specific differences in the capacity to produce IFN-γ after mitogenic stimulation (Table 3). Moreover, neither the expression of IFN-γ mRNA nor that of IL-4 mRNA differed between both lines, although the expression of IL-4 was slightly, but not significantly, greater in APO-SUS rats than in APO-UNSUS rats (p = 0.06; Table 4). However, the relative contribution of Th1 cells versus Th2 cells, as expressed in terms of the ratio IFN mRNA/IL-4, was significantly greater in APO-UNSUS rats than in APO-SUS rats (p = 0.03; Table 4).

DISCUSSION

The present study confirms and expands our previous findings that the susceptibility to EAE was significantly smaller in APO-SUS rats than in APO-UNSUS rats; when compared with APO-UNSUS rats, the severity of clinical symptoms of EAE was significantly less and the onset was significantly delayed (see Fig. 1 and Table 1 in Cools et al., 1993). In contrast, APO-SUS rats have a significantly larger response to infection with the nematode T. spiralis than APO-UNSUS rats: the level of parasite-specific IgE was significantly higher in APO-SUS rats than in APO-UNSUS rats, although the levels of parasite-specific levels of IgA and IgG did not differ between both lines in this model for Th2-dependent infectious diseases (Table 2, Fig. 2). In line with these data, the...
The present study shows that the relative contribution of Th1 and Th2 type responses significantly differed between both lines; as shown in Table 4, the ratio of the mRNA expression for the Th1 cytokine IFN-\(\gamma\) and for the Th2 cytokine IL-4 in splenocytes was much smaller in APO-SUS rats than in APO-UNSUS rats. These data together show that APO-SUS and APO-UNSUS rats show groupspecific differences in their susceptibility to inflammatory and infectious diseases, respectively.

Given the features of APO-SUS and APO-UNSUS rats mentioned in the introductory remarks, it can be concluded that the structure and reactivity of the neuroendocrine system of APO-SUS and APO-UNSUS rats is consistently coupled to a group-specific reactivity of the immune system in two fundamentally different disease models, namely the EAE model for a Th1-dependent autoimmune disease and the immune response to infection with the nematode *T. spiralis* for a Th2-dependent infectious disease.

The question arises whether the group-specific differences in the structure and reactivity of the HPA axis actually direct the group-specific differences in the balance between the responses of Th1 and Th2 cells. As mentioned in the introductory remarks, APO-SUS rats have higher plasma levels of ACTH at rest and in response to a stressor (Rots et al., 1996b). Moreover, stress-induced increases in corticosteroids are higher and last longer in APO-SUS animals (Rots et al., 1996b). Glucocorticoids are known to be capable of favouring a Th2 type of response. In *in vivo* administration of glucocorticoids to cultures of murine T cells selectively inhibits the response of Th1 cells (Daynes and Araneo, 1989; Daynes et al., 1990). In addition, in the presence of glucocorticoids, the differentiation and/or activation of Th2 cells is favored (Daynes and Araneo, 1989; Daynes et al., 1990). Furthermore, stress-induced increases in glucocorticoids can stimulate production of the Th2 cytokine IL-4 (Moynihan et al., 1994). Glucocorticoids not only favor the production of Th2 cytokines over Th1 cytokines but are also capable of enhancing the secretion of IgE by B cells in the presence of IL-4 (Nusslein et al., 1994). These data, together with the group-specific differences in susceptibility to Th1- and Th2-dependent immune diseases, give rise to the hypothesis that the group-specific differences in the structure and, especially, reactivity of the HPA axis direct the balance between the responses of Th1 and Th2 cells in APO-SUS and APO-UNSUS rats.

The role of HPA axis reactivity in the inflammatory process in the disease EAE has been suggested in other animal models as well. In the inbred strain of Lewis rats, which are highly susceptible to EAE, it has been shown that the responsiveness of the HPA axis is impaired (Sternberg et al., 1989a,b). The impaired functioning of the HPA axis in Lewis rats has been ascribed to a defect in the hypothalamic secretion of CRH (Sternberg et al., 1989b). In this respect it is of interest that APO-UNSUS animals express lower levels of CRH mRNA in the paraventricular nucleus of the hypothalamus than APO-SUS animals (Rots et al., 1995). Administration of glucocorticoids to inflammatory autoimmune disease-sensitive Lewis rats renders them into resistant animals (Sternberg et al., 1989a,b). On the other hand, resistant Fischer F344 rats can be rendered into highly susceptible animals by administration of the glucocorticoid receptor antagonist RU 486 (Sternberg et al., 1989a,b). In the mouse model, two inbred strains have been described that differ in the dominance of responses of Th1 or Th2 cells as well as in the reactivity of the neuroendocrine system. BALB/c mice respond predominantly with a Th2 type response, whereas C57Bl/b6 mice respond with a Th1 type response (Scott et al., 1989; Heinzl et al., 1991). It is of interest that these two strains display differences in the reactivity of the HPA axis that are similar to the differences between APO-SUS and APO-UNSUS rats: stress-induced increases in BALB/c mice are larger than in C57Bl/b6 mice (Shanks et al., 1994). Together, these data support the hypothesis that the structure and, especially, the reactivity of the HPA axis direct the Th1/Th2 balance.

In comparison with the above-mentioned animal models, the model of APO-SUS and APO-UNSUS rats has several advantages, of which only two are mentioned below. First, the procedure used to breed APO-SUS and APO-UNSUS rats guarantees the maintenance of the originally present genotypic heterogeneity, apart from the alleles at the loci involved in the determination of the selected traits; this matches the human situation far better than animal models with different inbred strains of rodents because such inbred strains, unlike humans, are each marked by a genotypic uniformity. Second, the available knowledge about group-specific differences in structure in the brain and body, as well as in behavior of APO-SUS and APO-UNSUS rats, is far greater than that of the mentioned inbred strains. Such knowledge is a prerequisite for analyzing additional mechanisms and factors that modulate, control, or direct individual-specific differences in susceptibility to inflammatory and infectious diseases. In this respect, it is relevant to mention that the group-specific differences in the structure and reactivity of the brain of APO-SUS and APO-UNSUS rats are consistently and causally coupled to group-specific differences in behavioral responses to internal and external challenges (coping styles). This makes these rats very useful models for studying the complex relation between individual-specific vulnerability for immune diseases and different coping styles.

Recently, we have found that APO-SUS and APO-UNSUS rats differ also in the adrenergic reactivity of the peripheral and CNS. Apart from the finding that the basal plasma level of adrenaline is lower in APO-SUS rats than in APO-UNSUS rats that may result in relatively hypersensitive \(\beta_2\)-adrenergic receptors, the stress-induced increase in adrenaline is much higher in APO-SUS rats than in APO-UNSUS rats (Rots, 1995). Therefore, the adrenergic system may be more effective in modulating responses in APO-SUS rats than in APO-UNSUS rats. Cells of the immune system express \(\beta_2\)-adrenergic receptors and from *in vitro* experiments it is known that adrenaline can selectively influence the reactivity of Th1 or Th2 cells (Johnson and Gordon, 1981). The increase in intracellular cAMP after activation of \(\beta_2\)-adrenergic receptors

results in increased IL-4 production (Paul-Eugene et al., 1993; Lacour et al., 1994; Katamura et al., 1995). Moreover, β2-adrenergic agonists can stimulate IL-4-dependent IgE synthesis (Paul-Eugene et al., 1993, 1995). We have data showing that β2-adrenergic agonist inhibit IFN-γ production, resulting in a shift toward Th2 type responses (A. Kavelaars, unpublished data). Thus, the relatively increased responsiveness of β2-adrenergic receptors in APO-SUS rats may also contribute to the relatively increased ratio of IL-4 over IFN-γ production. Therefore, the difference in Th1/Th2 balance between APO-SUS and APO-UNSUS animals could also be partly a result of the difference in the reactivity of the adrenergic system.

In conclusion, our data from the in vivo experiments are consistent with the hypothesis that the high reactivity of the HPA axis in APO-SUS animals can facilitate differentiation to Th2 type effector cell response and enhance IgE secretion, resulting in high IgE titers after infection with T. spiralis. Conversely, the low reactivity of the HPA axis in APO-UNSUS rats results in susceptibility to inflammatory autoimmune disease that is mediated via Th1 type T cells.
