Abstract. Compensation of transverse momentum is studied in $\pi^+p$ interactions at 250 GeV/c. Significant $p_T$ transfer is found between c.m.s. hemispheres. With respect to the beam axis transverse momentum is compensated over the whole event, with respect to the sphericity axis mainly within one hemisphere. The highest $p_T$ in the event is mainly compensated by increased multiplicity. The QGSM and FRITIOF models qualitatively reproduce these effects, but important differences are observed.

1 Introduction

Besides the longitudinal direction of a high energy collision, the transverse plane contains important information on the production mechanism. Of particular interest for the construction of parton models is the way in which transverse momentum $p_T$ is compensated within the final state of a collision. In early studies [1], $p_T$ was found to be compensated over a range in rapidity compatible with the total rapidity range available.

In [2] it has been shown that mini-jets with $|p_T|$ more than a few GeV/c become important at energies exceeding ISR energies. Many authors have suggested that, at high energies, mini-jets are responsible not only for the global properties, such as the rapid increase of the total cross-section and the average charge multiplicity, but also for local correlations, such as fluctuations of multiparticle production and the mechanism of $p_T$-compensation [3–12]. To trace possible differences in the particle production mechanism, it is interesting to compare $p_T$-compensation in inclusive reactions with that in events with high $p_T$-production.

An elegant method to study $p_T$ compensation in detail has been suggested in [13] and applied to heavy ion collisions in [14]. In this paper, the method proposed in [13] is used for $\pi^+p$-interactions at 250 GeV/c. The role of individual particles is studied in the compensation of the total $p_T$ in each hemisphere, with respect to the beam, as well as to the sphericity axis. In addition, compensation of the highest $p_T$ in the event is investigated. A related analysis in terms of longitudinal and transverse collective variables is performed in [15].

Two versions of the FRITIOF model (FRITIOF 6.0 and FRITIOF 7.0) and the Quark-Gluon-String Model (QGSM) are used for comparison with the experimental data.

In Sect. 2, the experimental procedure and the statistics used for the analysis are presented. Section 3 contains a brief description of the models. The method is recalled and the data are compared with the model predictions in Sect. 4. Conclusions are given in Sect. 5.
2 The experiment

The experiment has been performed with the European Hybrid Spectrometer (EHS), using a meson-enriched beam from the SPS accelerator. The analysis is based on results of the reconstruction of events in the hydrogen filled rapid cycling bubble chamber RCBC, used as a vertex detector, and a downstream spectrometer. A detailed description of the experimental set-up is given in [16, 17] and references therein.

Events are accepted when measured and reconstructed charge multiplicity are consistent, charge balance is satisfied and no electron is detected. Only events with all tracks satisfying our quality criteria are included in this analysis. Two-prongs are excluded.

For momenta $p_{LAB} < 0.7$ GeV/c, the range in the bubble chamber and/or the change of track curvature is used for proton identification. In addition, a visual ionization scan has been used for $p_{LAB} \leq 1.2$ GeV/c on 62% of the $\pi^+$ sample. Particles identified as protons are given proton mass. Particles with momenta $p_{LAB} > 1.2$ GeV/c are not identified in the present analysis and are treated as pions.

Single diffractive events (from $\pi^+$ or $p$ dissociation) are defined as events of charged particle multiplicity $n \leq 6$ with at least one positive particle having Feynman $|x_F| \geq 0.88$ and are removed from the sample.

After these cuts, our sample consists of 41,533 non-single-diffractive $\pi^+ p$ events with charged particle multiplicity $n > 2$. A correction is applied for the loss of events during measurement and reconstruction by normalization to the topological cross section data [16]. The average charge multiplicity of inelastic non-single diffractive events is $9.23 \pm 0.14$ [18].

3 Quark models

A comparison is performed with three models: the Lund type models FRITIOF 6.0 [19] and FRITIOF 7.0 [20] and the Quark-Gluon-String model QGSM [21].

The FRITIOF mechanism of producing particles can be characterized as "total diffraction", in which each of the colliding particles is excited to form a dipole. During the collision between the two hadrons, many uncorrelated momentum transfers occur. This leads to a reaction of the evolving strings as if they had been worked upon by a single momentum transfer. The color separation causes gluonic bremsstrahlung. The beam meson fragments like a quark-antiquark chain in $e^+ e^- -$annihilation and the target-nucleon dipole like a quark-diquark chain in lepton-nucleon collisions. In both versions, default parameters are used (e.g. mean primordial $p_T$ for string ends equal to 0.25 (GeV/c)$^2$ for version 6.0 and 0.30 (GeV/c)$^2$ for version 7.0, width of the Gaussian transverse momentum distribution for primary hadrons $\sigma_T = 0.35$ GeV/c and 0.405 GeV/c, respectively).

The main difference between versions 6.0 and 7.0 is that hard (Rutherford) parton scattering is included in 7.0, but not in 6.0.

The QGSM is based on dual topological unitarization. In addition to 2 strings being formed between valence quark and antiquark and between quark and diquark of the colliding hadrons, respectively, strings are formed between sea quarks and antiquarks of the primordial particles. The string breaking algorithm of QGSM is described in [21]. At the string break-up, the transverse momenta of the sea quark $p_q$ and antiquark $-p_{\bar{q}}$ are assumed to be distributed according to $P(p_T^2) = 3 b/[\pi(1 + b p_T^2)^2]$ with $b = 0.34$ (GeV/c)$^{-2}$. The diquark from the proton compensates the total transverse momentum of the other quarks (antiquarks). Due to an increase of the number of quark-gluon strings with increasing energy, the average $p_T$ of quarks and antiquarks, and via the compensation that of the diquark, increases. The transverse momentum of valence quarks is distributed according to $P(p_T^2) = c \exp(-c p_T^2)/\pi$ with a slope parameter $c = 10$ (GeV/c)$^{-2}$. QGSM does not include any hard parton scattering.

The main differences between the models used for comparison with the experimental data are colour exchange (present in QGSM, but not in FRITIOF) and hard parton scattering included only in FRITIOF 7.0. So, a comparison of the experimental data with model predictions is expected to elucidate the role of hard processes and the role of colour exchange at our energies. All three models give reasonable descriptions of the gross features of the data in terms of multiplicity, single particle $p_T$ and rapidity distributions, and as such can be used as background for observation of any multi-jet effects or any other phenomena in $p_T$-generation. Rather than attempting to tune the models to the data presented in this paper, we restrict ourselves to a comparison in terms of the default parameters. Retuning of the parameters on the basis of all NA 22 results is foreseen in later stage.

Two-prong and diffractive events are excluded from the Monte Carlo events by the same cuts as used for the data. Proton misidentification is treated as in the data.

4 Results

4.1 Transverse momentum compensation between hemispheres

The total transverse momentum of charged particles in one c.m.s. hemisphere gives a first estimate of typical $p_T$-values of groups of particles. It sets the scale of any collective effects in the transverse plane. Neglecting neutral particles, total transverse momentum vectors $\mathbf{Q}_q$ and $\mathbf{Q}_f$ are defined over all charged particles in backward (proton) and forward ($\pi^+$) hemispheres, respectively, as

$$
\mathbf{Q}_q = \sum_{j=1}^{k} \mathbf{p}_{T,q,j}, \quad \mathbf{Q}_f = \sum_{j=k+1}^{n} \mathbf{p}_{T,f,j},
$$

where $n$ is the total number of charged particles in the event and $k$ that of charged particles in the backward hemisphere. The average values of the magnitudes of
comparison to a statistical model described in the text (dotted), to 
latter that there is significantly more pr-exchange be­
ically larger than the average transverse momentum 
values of <0/> and (Qb) (~ 1 GeV/c) observed are signif­

tum conservation imposes some constraints on the 
tween hemispheres in the data than in the models. 
cant pT -exchange takes place between hemispheres, the 
ected in which can be derived analytically. The 
structed, in which can be derived analytically. The 

where x = \frac{1}{2} \cos \Delta \varphi. Thus, in the statistical model the 
angular correlation between Q_f and Q_b does not depend on 
the magnitude of the Q vectors. The \frac{d\sigma}{d\Delta \varphi} distribu­
tion calculated according to this formula is shown in 
Fig. 1 as dotted line. It provides a satisfactory descrip­
tion of the data (taking into account the deficiency of the 
approximation used).
Model predictions are presented as dot-dashed line 
(FRITIOF 6.0), full line (FRITIOF 7.0) and dashed line 
(QGSM) and are also in agreement.
To understand how the transverse momentum is 
distributed inside the two hemispheres and to understand 
the role of the central region, we distinguish particles 
from the central region (|x_f| < 0.2) and define the vectors 
Q_f and Q_b for this region, separately. The average values 
of the vectors Q_f and Q_b in this region are presented 
in columns 4 and 5 of Table 1. Differences between <Q_f> and <Q_b> can now be due to neutral particles and to 
the asymmetry of the x_f distribution of charged particles. 
The models also underestimate the total transverse mo­
mentum in the central regions.
Large p_T-exchange between the two hemispheres leads to strong correlations between the values of <Q_f> and <Q_b>. In Fig. 2, the dependence <Q_f(Q_b)> and 
<Q_b(Q_f)> is presented for all charged particles, as well 
for particles in the central region, together with the mod­
el predictions. The models are below the experimental 
points for all values of Q_f and Q_b. This is in agreement 
with the observation made for the averages in Table 1, 
but does not of itself mean that the correlations must 
also come out too low in these models. Indeed, an in­
crease of <Q_f> and <Q_b> with increasing Q_b and Q_f, 
respectively, is seen for data and models.
To give a qualitative estimate of the strength of the 
correlation effect, we fit the observed increase by the 
usual linear functions
\begin{equation}
\langle Q_f \rangle = a_f + b_f Q_f, \quad \langle Q_b \rangle = a_f + b_f Q_f, 
\end{equation}
where three vectors Q_f, Q_b and the total transverse momentum 
of neutrals Q_o must sum up:
\begin{equation}
Q_f + Q_b + Q_o = 0. 
\end{equation}
Let us assume the same Gaussian ansatz for each Q 
vector. Then the differential cross section can be written 
in the form:
\begin{equation}
\frac{d\sigma}{dQ_f dQ_b dQ_o} = \prod_i \exp(-b Q_i^2) \delta^{(2)}(\sum Q_i). 
\end{equation}

Fig. 1 shows the distribution in the azimuthal angle 
\Delta \varphi between Q_f and Q_b, as well as between 
charged particles and neutral pions. The average values 
\langle Q_f \rangle and \langle Q_b \rangle are presented 
in columns 2 and 3 of Table 1, together with the corre­sponding model predictions. The values of \langle Q_f \rangle 
and \langle Q_b \rangle (~1 GeV/c) observed are sig­nificantly larger than the average transverse momentum 
of single particles and also larger than expected from 
FRITIOF and QGSM. The former means that significa­tant p_T-exchange takes place between hemispheres, the 
latter that there is significantly more p_T-exchange 
between hemispheres in the data than in the models.

A difference exists between the \langle Q_f \rangle and \langle Q_b \rangle values in columns 2 and 3 of Table 1. This difference is ex­plained from neutral particles not included in the analy­sis, since otherwise Q_b = - Q_f would follow for every 
event from momentum conservation.

Figure 1 shows the distribution in the azimuthal angle 
\Delta \varphi between Q_f and Q_b. A deviation from \Delta \varphi = \pi means that the role of neutral particles is not negligible. How­ever, even when including neutrals, transverse momen­tum conservation imposes some constraints on the \Delta \varphi distribution. A simple statistical model can be con­structed, in which \frac{d\sigma}{d\Delta \varphi} can be derived analytically. The
excluding the first points. Results of the fits are presented in Table 2. Strong positive correlations (measured by the slope $b$) are observed in the experiment between the total hemispheres, as well as in the central region. For the total hemispheres, FRITIOF 6.0 underestimates the slope, while in QGSM and FRITIOF 7.0 the slopes are in agreement with experiment. All models underestimate the slope in the central region.

The correlation between the values of $Q_f$ and $Q_b$ is influenced by the correlation between the number of particles produced into the forward and backward hemispheres. Assuming absence of $p_T$-correlations inside a hemisphere and neglecting transverse momentum conservation, one can derive the relation

$$ \langle Q_f^2 \rangle \sim k \langle p_T^2 \rangle. $$

For the case that the slope of $Q_f$ of particles in the forward hemisphere is independent of that in the backward hemisphere, one can expect the same strength of correlation between $Q_f^2$ and $Q_b^2$ as for $\langle n_f(n_b) \rangle$. These forward-backward multiplicity correlations have been studied in our experiment in [23]. The slopes of $\langle Q_f^2(Q_b^2) \rangle$ for the total hemispheres, as well as for the central region, are presented in Table 3, together with the model predictions and with the slopes for the forward-backward multiplicity correlations. A strong positive correlation is observed between $Q_f^2$ and $Q_b^2$ defined for the total hemispheres. A comparison of the correlation strength in $Q_f^2$ and $n$ shows that the parameter $b$ is much larger when evaluated in $Q_f^2$. The strength of correlation in $n$ increases when limiting the analysis to the central region, but the difference remains very big even there. The models underestimate the slopes.

Since the forward-backward multiplicity correlations are weaker than the $Q_f^2(Q_b^2)$-correlations, one can conclude that a correlation exists between $p_T$-values of particles from different hemispheres. A comparison of experimental slopes with model predictions shows a big discrepancy between models and experiment for the central region and for the total hemispheres.

So, significant transfer of $p_T$ is observed between forward and backward hemispheres in the cms, larger than predicted by FRITIOF and QGSM. The $p_T$-transfer is mainly absorbed by the large number of particles produced in the central region. This means that the mechanism of multiparticle production leads to a collective effect of large-$p_T$ groups of particles in the central region. No such mechanism exists in the models examined. Semi-hard processes, such as mini-jet production, could be responsible for this effect.

In this section, we study the role of individual charged particles in $p_T$-compensation, within the same and between opposite hemispheres. The projections of $p_T$ on to the $Q_f$ and $Q_b$ directions are calculated for each particle. In order to remove a distortion resulting from the projection of the particle momentum on to itself, vectors $Q_{f,i}$ and $Q_{b,i}$ are defined for each particle $i$ by the sum over the remaining particles in a given hemisphere as

$$ Q_{b,i} = \sum_{j \neq i} p_{T,j}, \quad Q_{f,i} = \sum_{j \neq i} p_{T,j}. $$
We study the components of the transverse momentum in the direction of $Q_f$ and $Q_b$, respectively, as a function of rapidity $y$, compared to predictions from FRITIOF 6.0 (dot-dashed), FRITIOF 7.0 (full) and QGSM (dashed).

In Fig. 3 the dependence of $p_{T,i}$ on particle's rapidity $y$ is shown for all charged particles, in comparison with the models. Small, but negative values of $p_{T,i}$ over the whole event. Small values of $p_{1,i}$ and $p_{2,i}$ mean that, on average, the direction of $p_{T,i}$ of particle $i$ correlates only weakly with the direction of the residual transverse momentum of a hemisphere. The largest negative values are observed in that hemisphere in which particle $i$ is produced. So, compensation of a particle's transverse momentum is stronger in its own hemisphere than in the opposite hemisphere.

In tracing effects originating from local (essentially within one hemisphere) and from global (between the two hemispheres) $p_T$-compensation, it is interesting to compare the results obtained with respect to the beam axis to those obtained with respect to the sphericity axis. By definition, effects of global $p_T$ exchange between initial particles are suppressed in an analysis with respect to the latter.

The sphericity frame $p_{s,i}$ distributions, are compared with the models in Fig. 5, where now $y$ is defined with respect to the sphericity axis. The forward hemisphere w.r.t. the sphericity axis is chosen at random event by event, so that the $p_{s,i}$ distributions are forced to follow:

$$\langle p_{s,i}^\text{ph}(y) \rangle = \langle p_{s,i}^\text{ph}(-y) \rangle .$$

The component of $p_{T,i}$ in the direction of the residual transverse momentum of the same hemisphere is negative.
and has larger absolute value than in Fig. 3. All models roughly describe the $p_T$-compensation inside the hemisphere of the detected particle, but the model curves are broader in $y$ than the data. On the other hand, the component of $p_T$ in the direction of the opposite hemisphere is small in the models, but has clearly positive values in experiment.

The average of component $p_T^{sph}$ in the sphericity system is shown in Fig. 6 as a function of rapidity $y$ along the sphericity axis. The random choice of the forward direction here defines the form of the distribution to follow $\langle p_T^{sph}(y) \rangle = -\langle p_T^{sph}(-y) \rangle$. Indeed, in the new basis, the picture of compensation changes, for experiment as well as for the models. The values of $\langle p_T^{sph} \rangle$ at $|y| \approx 2$ are much larger than those of $\langle p_T \rangle$ in Fig. 4 and $p_T$ exchange is considerably larger in exeriment than in the models. The differences between the models themselves are largely reduced.

Transfer of $p_T$ between forward and backward hemispheres becomes more evident in the new (sphericity) basis. A particle which compensates the residual transverse momentum of the own hemisphere is positively correlated with the direction of the total transverse momentum of the opposite hemisphere. Absence of these positive correlations in the models shows that $p_T$-exchange between hemispheres is smaller in the models than in experiment.

So, the role of a particle in the compensation of the total transverse momentum of its own hemisphere becomes more essential when evaluated in the new basis than with respect to the beam axis (Figs. 5, 6 as compared to Figs. 3, 4). Long-range positive correlations become evident between a single particle from one hemisphere and the total $p_T$ of the opposite hemisphere (Fig. 5). Both FRITIOF versions and QGSM qualitatively describe the experimental data, but the models predict a $p_T$-compensation region wider in $y$ than observed in experiment (Fig. 5). In the models practically no long-range positive correlations are expected between $p_T$ of a particle from one hemisphere and the direction of the total $p_T$ of the opposite hemisphere (Fig. 5).

### 4.3 High-$p_T$ compensation analysis

To study the properties of production of particles with transverse momentum larger than average, the compensation of the highest charged particle transverse momentum in the event is investigated with respect to the sphericity axis. Only events with at least one charged particle (trigger) with $p_T > 1.5$ GeV/c are accepted in the analysis. To exclude distortion of the $p_T$-distribution by fast particles from the fragmentation regions and by phase space limitations, only triggers with $|y| < 2.0$ are accepted. The cross section of selected events (1065 events) is given in column 2 of Table 4.

For the selected events, the vectors $Q_{str}$ and $Q_{str}$ are defined for triggers w.r.t. the sphericity axis. In Fig. 7, $\langle p_T^{str} \rangle$ and $\langle p_T^{str} \rangle$ are shown as a function of trigger rapidity, and $\langle p_T^{str} \rangle$ in Fig. 8. Due to the random choice of the forward hemisphere similar symmetry properties are expected for Figs. 7 and 8 as observed in Figs. 5 and 6. Due to limited statistics, these properties are not perfect here. In Fig. 7, a deep minimum is observed in the trigger hemisphere. This means that all other particles within the trigger hemisphere tend to compensate the large $p_T$ of the trigger. Only small positive correlations are observed between the $p_T$ of the trigger and the total $p_T$ of particles in the opposite hemisphere. QGSM reproduces the trend in the experimental data, but not FRITIOF.

A detailed analysis of trigger compensation is useful in tracing semi-hard processes in multiparticle production and is performed in the following w.r.t. the beam axis.

A comparison of global event characteristics with model predictions of FRITIOF and QGSM is presented...

in Table 4. The average charge multiplicity $\langle n \rangle$ is larger in events containing a particle with $p_T > 1.5$ GeV/c than the $\langle n \rangle \approx 9.23 ± 0.14$ observed for our inelastic non-single diffractive events in [18]. Reasonable agreement is observed between experiment and QGSM. FRITIOF 6.0 cannot reproduce the cross section. On the other hand, FRITIOF 7.0, which includes hard parton scattering, underestimates their multiplicity.

Let us now define a transverse momentum flow as the sum of transverse momentum components in the trigger direction ($\Delta \phi < \pi/2$) and opposite to the trigger direction ($\Delta \phi > \pi/2$), in comparison to FRITIOF 6.0 (dot-dashed), FRITIOF 7.0 (full) and QGSM (dashed).

$$L(\Delta y) = \sum_{\text{charged particles}} p_T \cos \Delta \phi.$$  

Here, $\Delta \phi$ is the azimuthal angle between the trigger and the particle. The transverse momentum flow averaged over all events is shown in Fig. 9 as a function of $\Delta y$, separately for negative and positive particles, along the trigger direction in the transverse plane ($\Delta \phi < \pi/2$) and in opposite direction ($\Delta \phi > \pi/2$). The distributions have a maximum at small $\Delta y$. FRITIOF 6.0 predicts far too small a flow of positive particles in both directions. Near the trigger ($\Delta y \leq 2$) also QGSM and FRITIOF 7.0 underestimate the $p_T$ flow of positives in both directions. Also for negatives none of the models is able to describe the flow simultaneously for $\Delta \phi < \pi/2$ and $\Delta \phi > \pi/2$.

The discrepancies in $L$ may be connected with deviations between models and experiment in the average transverse momentum flow per particle, $\langle p_T \cos \Delta \phi \rangle$, or in number of particles following the trigger or going into the opposite direction. The analysis of $\langle p_T \cos \Delta \phi \rangle$ in Fig. 10 shows practically no dependence on $\Delta y$. The
average values are \( \langle p_T \cos \phi \rangle \approx 0.2 \) in the whole region of \( \Delta y \) for particles in the trigger direction and \( \langle p_T \cos \phi \rangle \approx 0.3 \) for particles in the opposite direction. The models overestimate these values for negative particles.

In Fig. 11 the number of positive and negative particles (not including the trigger) is presented in the trigger direction and in the opposite direction. All models underestimate the number of positive particles in both directions. QGSM describes the number of negatives reasonably well, but both FRITIOF versions are too flat.

From Figs. 9, 10, 11 it follows, that the trigger \( p_T \) is compensated mainly by a large number of particles with average \( p_T \), emitted opposite to the trigger direction. This result agrees with observations made in [24] in terms of transverse energy (see also the model argumentation of [25]). The details of the compensation mechanism are not accounted for by the models considered in our analysis.

The charge flow \( \langle n^+ - n^- \rangle \) along the trigger (not including the trigger) and in opposite direction is shown in Fig. 12, together with the model predictions. Both FRITIOF 6.0 and QGSM, not including hard parton scattering, underestimate the charge flow opposite to the trigger. FRITIOF 7.0 describes the experimental data very well. It has, however, been verified that this success is not due to the presence of hard scattering in the latter.
5 Conclusions

An analysis has been performed of transverse momentum compensation in $\pi^+\pi^-$-interactions at 250 GeV/c. The main results can be summarized as follows.

1. Significant transverse momentum transfer is observed between c.m.s. hemispheres. The transfer is larger than predicted by FRITIOF or QGSM. The transfer is mainly absorbed by the large number of particles in the central region.

2. Non-trivial correlations (beyond the multiplicity effect) exist between the total $p_T$ of charged particles in forward and backward hemispheres.

3. Transverse momentum compensation with respect to the sphericity axis mainly takes place within one hemisphere. The models predict a compensation region wider in $y$ than observed in experiment.

4. The analysis of the compensation of the highest $p_T$ ($>1.5$ GeV/c) shows that the large $p_T$ of the trigger is compensated mainly by particles in the trigger hemisphere.

5. The analysis of events with a trigger particle shows that the average charge multiplicity of such events is larger than that for all events. Significant flow of $p_T$ and number of particles is observed along the trigger direction in the transverse plane and in opposite direction. This means that the high-$p_T$ compensation is local in $y$-range and the mechanism of high-$p_T$ production leads to collective effects. Neither of the examined models can reproduce these effects in detail, but QGSM is in better agreement with experiment than FRITIOF.

6. Within FRITIOF, a large cross section for high $p_T$ trigger events can be obtained only by FRITIOF 7.0, where hard parton scattering is included. So, hard processes cannot be neglected even at our energies.

Acknowledgments. We are grateful to the III. Physikalisches Institut B, RWTH Aachen, Germany, the DESY-Institut für Hochenergiephysik, Zeuthen, Germany, the Department of High Energy Physics, Helsinki University, Finland for early contributions to this experiment. This work is part of the research programme of the "Stichting voor Fundamenteel Onderzoek der Materie (FOM)", which is financially supported by the "Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO)". We thank further NWO for support of this project within the programme for subsistence to the former Soviet Union (07-13-036).
