A B S T R A C T

EEG and eye-tracking provide complementary information when investigating language comprehension. Evidence that speech processing may be facilitated by speech prediction comes from the observation that a listener’s eye gaze moves towards a referent before it is mentioned if the remainder of the spoken sentence is predictable. However, changes to the trajectory of anticipatory fixations could result from a change in prediction or an attention shift. Conversely, N400 amplitudes and concurrent spectral power provide information about the ease of word processing the moment the word is perceived. In a proof-of-principle investigation, we combined EEG and eye-tracking to study linguistic prediction in naturalistic, virtual environments. We observed increased processing, reflected in theta band power, either during verb processing - when the verb was predictive of the noun - or during noun processing - when the verb was not predictive of the noun. Alpha power was higher in response to the predictive verb and unpredictable nouns. We replicated typical effects of noun congruence but not predictability on the N400 in response to the noun. Finally, anticipatory fixations were predictive of spectral power during noun processing and the length of time fixating the target could be predicted by spectral power at verb onset, conditional on the object having been fixated. Overall, we show that combining EEG and eye-tracking provides a promising new method to answer novel research questions about the prediction of upcoming linguistic input, for example, regarding the role of extralinguistic cues in prediction during language comprehension.

1. Introduction

Listeners can process spoken language incredibly quickly. One mechanism that is thought to help with such fast processing is the prediction of upcoming linguistic input. Eye-tracking studies, such as a long tradition of work using the visual world paradigm (VWP), have been fundamental in showing that listeners can use visual and linguistic constraints to predict upcoming referents prior to them being mentioned (Allopenna et al., 1998; Altmann and Kamide, 1999). However, a change to the trajectory of eye movements can be difficult to interpret (Huettig et al., 2011), as it could indeed reflect a shift in processing linguistic or semantic input, but also, alternatively, a mere shift in visual attention, without a change in linguistic processing. More specifically, in regards to the prediction of upcoming words, it is possible for eye movement patterns to differ, but the underlying prediction to remain the same. Eye-tracking can reliably tell us that listeners predict upcoming information, but the absence of anticipatory looks cannot with full certainty be taken to mean that there is no prediction. In contrast, while event-related potential (ERP) amplitudes, time-locked to the onset of the predicted word, provide limited information about whether a word has been predicted before its onset, they can provide information about the ease of word processing the moment the word is perceived. Combining these measures within a single study and single analysis could therefore help to answer more nuanced theoretical questions about language comprehension (Knoeferle, 2015) and the types of cues used to inform predictions.

Listeners may rely on both linguistic and extralinguistic cues to anticipate upcoming speech content. The extent that predictions are informed by extralinguistic cues is unclear. For example, the speaker’s facial expressions, eye gaze and gestures could provide useful information about upcoming and concomitant spoken input (Holler and Levinson, 2019; Perniss, 2018; ter Bekke, Drijvers and Holler, 2020). Moreover, disfluencies in speech (filled hesitations, repairs, silent pauses) are thought to provide information about the certainty of the speaker, or the ease of producing the upcoming word (Bortfeld et al., 2001; Brennan and Williams, 1995; Fraudorf and Watson, 2014; Schacter et al., 1991; Smith and Clark, 1993). Listeners have been shown to predict that the speaker will utter less frequent words or discourse-new information after producing a disfluency, rather than highly frequent or discourse-given information (Arnold et al., 2003; Arnold and Tanenhaus, 2011; Arnold et al., 2004). In a recent virtual reality (VR) study, Huizeling et al. (2022) observed a reduced proportion of fixations towards a predictable referent after the constraining verb was followed by a hesitation (e.g. “cutting down uhh the tree”), compared to if the sentence was spoken fluently. Instead, participants’ eye gaze moved towards the virtual speaker upon hearing the hesitation. It is unclear whether this shift in eye gaze signifies the listener losing confidence in or even abandoning their prediction altogether. Alternatively, this shift in gaze may indicate a shift in visual attention towards the speaker, either to search for meaningful visual bodily signals to aid in language comprehension or in response to the saliency of the disrupted flow of speech.

Measuring ERPs, such as the N400, in response to the predicted word onset could help to better understand the role of extralinguistic cues, like disfluencies and gestures, on predictive language processing. The N400 is a negative ERP that typically occurs around 400ms after stimulus onset, with a centrotopral topography. It is thought to reflect the amount of new information to be integrated with the prior semantic context (Brothers and Kuperberg, 2021; Hagoort et al., 2001; Dambacher et al., 2006; Federmane and Kutas, 1999; Kutas and Hillyard, 1980; Nieuwland et al., 2020). The N400 amplitude is larger (more negative) when a word is more difficult to integrate with the prior sentential context. A larger N400 amplitude is therefore observed if a word is semantically incongruent with the prior content of the sentence (Hagoort et al., 2004; Kutas and Hillyard, 1980; Nieuwland and van Berkum, 2006). Moreover, as the context provided by the sentence becomes more constraining and upcoming words become more predictable, the N400 amplitude decreases (Dambacher et al., 2006; Federmane and Kutas, 1999; Kutas and Hillyard, 1984; Terporten et al., 2019). A larger N400 amplitude is also observed when listeners are presented with an image that is incongruent with the coinciding linguistic input (Federmane and Kutas, 2001; Ganis et al., 1996; Knoeferle et al., 2011; Ozyurek et al., 2007; Sitnikova et al., 2008; Tromp et al., 2018; Willems et al., 2008a,b), however, with a more anterior topography. If disfluencies in speech cause listeners to lose confidence in or disregard their prediction, then the N400 amplitude in response to predictable nouns might be expected to be larger if the noun is preceded by a disfluency, relative to if the sentence was spoken fluently (Corley et al., 2007; MacGregor et al., 2010). Before such hypotheses can be tested in more naturalistic virtual environments, we first need to test whether effects of sentence predictability can be measured in the EEG signal while participants are engaged in VR (Tromp et al., 2018).

The event-related signal in a post-N400 time window (e.g. 600-1000ms) has also been found to be sensitive to the constraints employed by the sentence context. An enhanced late posterior positivity has been found in response to semantic information that is incongruent with the preceding context, whereas an enhanced late anterior positivity has been associated with lexical items that are plausible but unexpected in highly constraining contexts (DeLong et al., 2014; Federmane et al., 2007; Quante et al., 2018; Thornhill and Van Petten, 2012; Van Petten and Luka, 2012). Where the anterior positivity is thought to reflect either updating, inhibiting an incorrect lexical prediction, or integrating unexpected semantic information with the prior context, the posterior positivity is thought to reflect the detection of conflict and a failure to integrate new information into the preceding context, leading to a reanalysis of the sentence context and altered expectations about the upcoming content (Brothers et al., 2020; Kuperberg et al., 2020; Rommers and Federmane, 2018; Van Petten and Luka, 2012). However, it should be noted that evidence that differential anterior and posterior post-N400 effects map onto different functions of language processing has so far been acquired from laboratory-based paradigms. It is not clear to what extent findings generalise to more natural language processing.

ERPs, such as the N400 and the post-N400 positivity, could provide useful information regarding the influence of sentence context constraints on word processing the moment the word is perceived and could provide information about the processing consequences of disfluencies. The brain’s response to sentence predictability has also been observed in ongoing neurophysiological oscillatory activity. Unlike ERPs, oscillations are sensitive to effects that are not phase-locked to a stimulus onset. This makes them particularly useful to study on-line predictions, which may form gradually with the build-up of context. Prysta and Lewis (2019) provide an informative review of oscillatory dynamics of sentence comprehension and anticipatory processing.

There is increasing evidence that alpha (8–12 Hz) and beta (13–30 Hz) power are reduced when the context of a sentence is highly constrained. Broadly, reductions in alpha and beta band power are associated with increased cognitive processing in the cortex, increased attention, memory encoding and memory retrieval (Foxe et al., 1998; Jensen and Mazaher, 2010; Klimesch et al., 1994). Increased alpha power is thought to reflect the suppression of cognitive processing in the cortex and inhibition (Klimesch et al., 2007; Strauß et al., 2014a,b). Lower alpha and beta power have been observed directly prior to a target word when the target word is predictable compared to unpredictable (Gastaldon et al., 2020; Leon-Cabrera et al., 2022; Molinaro et al., 2017; Pia et al., 2014; Rommers et al., 2017; Roos and Piai, 2020; Terporten et al., 2019; Wang et al., 2018) and in response to highly constraining compared to unconstraining information (Li et al., 2017). Moreover, lower pre-stimulus alpha power has been linked to increased effects of word congruence on N400 amplitudes (Lago et al., 2023). However, alpha/beta power modulation does not seem to be linearly modulated by constraint. Terporten et al. (2019) found the greatest alpha desynchronisation prior to the critical noun in moderately constraining sentences, followed by highly and then weakly constraining sentences. Unexpected words and incongruent visual information have been shown to result in lower alpha and beta power compared to expected words or congruent visual information (Rommers et al., 2017; Wang et al., 2012; Willems et al., 2008a). In contrast, two studies have found no effect of word predictability on alpha or beta power after word onset when the word was consistent with the sentence context (Rommers and Federmane, 2018; Terporten et al., 2019).

Oscillations in the theta band have been associated with a range of cognitive functions, and tend to increase with increased cognitive processing (Cavanagh and Cohen, 2022; Cavanagh and Frank, 2014; Demiralp and Başar, 1992; Klimesch et al., 1994). Within the language literature, increased theta power has been related to memory retrieval during sentence comprehension and when hearing repeated names or pronouns (Goopmans and Nieuwland, 2020; Heine et al., 2006; Meyer et al., 2015). Less attention has been devoted to reporting effects of predictability in the theta frequency band with EEG data. Prior to the critical noun onset, theta frequency modulations have been observed by constraining experimental conditions (Li et al., 2017) found no significant differences in theta frequency in response to high compared to low constraining verbs in written Chinese sentences. Higher theta power has been observed, however, in response to unexpected words compared to expected words, for both semantically plausible and anomalous continuations (Bastaansena and Hagoort, 2015; Li et al., 2017; Rommers et al., 2017; Willems et al., 2008a). It is thought that increased theta power reflects the increased effort to retrieve less predictable words from long term memory.
The large majority of studies discussed above have presented visual and/or auditory stimuli to individual participants in restricted laboratory set-ups that relatively poorly resemble the rich and dynamic situations of language processing in everyday life. An emerging realisation in psycholinguistic research is to move away from artificial laboratory experiments towards more ecologically valid, naturalistic paradigms, where language can be embedded in an enriched context (Hasson et al., 2018; Peeters, 2019). The rapidly growing VR industry means that it is now feasible to conduct psycholinguistic research in increasingly enriched naturalistic contexts, while maintaining the high level of experimental control afforded by laboratory experiments. In our recent work we have shown that people also make predictive eye movements in visually rich, naturalistic environments in the presence of a virtual speaker (Heyselaar et al., 2020; Huizeling et al., 2022). The presence of a virtual speaker shed new light on listeners’ behaviour when they hear a disfluency in speech (Huizeling et al., 2022). Rather than the listener’s eye gaze moving towards potential upcoming referents in the visual scene, participants looked towards the virtual speaker upon hearing a disfluency. This leaves an open question as to whether listeners lose confidence in their prediction in such instances, or wait for the sentence to become disambiguated. Obtaining the aforementioned eye gaze and electrophysiological measures concomitantly in naturalistic paradigms could provide information about the ease of word processing when listening to disfluent predictable sentences. However, it first needs to be established whether these two measures can be acquired in parallel while participants engage in VR.

Previously, combined EEG-eye-tracking experiments have been largely avoided due to eye movement artifacts, which can correlate with the variables of interest, contaminating the EEG data. One method to overcome this issue is to time-lock EEG analysis to the fixation onset to largely avoid eye movement artifacts, which can correlate with when participants engage in VR.

Established whether these two measures can be acquired in parallel and/or auditory stimuli to individual participants in restricted laborato- try set-ups that relatively poorly resemble the rich and dynamic situations of language processing in everyday life. An emerging realisation in psycholinguistic research is to move away from artificial laboratory experiments towards more ecologically valid, naturalistic paradigms, where language can be embedded in an enriched context (Hasson et al., 2018; Peeters, 2019). The rapidly growing VR industry means that it is now feasible to conduct psycholinguistic research in increasingly enriched naturalistic contexts, while maintaining the high level of experimental control afforded by laboratory experiments. In our recent work we have shown that people also make predictive eye movements in visually rich, naturalistic environments in the presence of a virtual speaker (Heyselaar et al., 2020; Huizeling et al., 2022). The presence of a virtual speaker shed new light on listeners’ behaviour when they hear a disfluency in speech (Huizeling et al., 2022). Rather than the listener’s eye gaze moving towards potential upcoming referents in the visual scene, participants looked towards the virtual speaker upon hearing a disfluency. This leaves an open question as to whether listeners lose confidence in their prediction in such instances, or wait for the sentence to become disambiguated. Obtaining the aforementioned eye gaze and electrophysiological measures concomitantly in naturalistic paradigms could provide information about the ease of word processing when listening to disfluent predictable sentences. However, it first needs to be established whether these two measures can be acquired in parallel while participants engage in VR.

Previously, combined EEG-eye-tracking experiments have been largely avoided due to eye movement artifacts, which can correlate with the variables of interest, contaminating the EEG data. One method to overcome this issue is to time-lock EEG analysis to the fixation onset to measure fixation related potentials (Dimigen et al., 2011). However, this is only possible with visually presented linguistic stimuli and not auditory stimuli. Recent advances in data processing have drastically improved the ability to correct for eye movement artifacts in the data (Dimigen, 2020). Although modern artifact correction techniques have been shown to be successful in computer-based reading and scene viewing paradigms, it is not clear to what extent such methods would be successful with EEG data recorded while participants are engaged in VR. Recording EEG in VR faces a number of additional challenges, such as muscle artifacts from head movements and potential interference from electrical noise. Before one can combine EEG and eye-tracking in naturalistic virtual environments to answer more nuanced research questions regarding the extent of extralinguistic cues on predictive processing, it is first vital to test to what extent it is possible to combine EEG, eye-tracking and VR to investigate predictive language processing.

1.1. The current study

The current study was a proof-of-principle investigation into the feasibility of simultaneously collecting EEG and eye-tracking data in VR to investigate the prediction of upcoming speech. EEG has previously been used successfully in VR settings both in our VR laboratory (Peeters, 2020; Raghavan et al., 2023; Tromp et al., 2018) and other laboratories (Badia et al., 2013). Recent studies have also begun to record EEG and eye-tracking simultaneously within free-viewing paradigms (Coco et al., 2020; Dimigen, 2020). Here we go one step further by combining eye-tracking and EEG in VR. We specifically wanted to test whether we could replicate effects of (a) the context constraint, and (b) the congruency of the sentence with the listener’s predictions, on eye gaze and electrophysiological measures, including ERPs and frequency power, during a free-viewing VR paradigm. Robust effects of predictability and congruency on the EEG signal would pave the way for future studies to answer new theoretical questions regarding the influence of extralinguistic cues, such as disfluencies, on predictive processing.

To this end, we conceptually replicated Experiment 1 from Huizeling et al. (2022). In a 3D VWP, Huizeling et al. (2022) tracked participants’ eye gaze in VR while they listened to predictable and unpredictable sentences. Here we additionally simultaneously recorded EEG. Sentences (pre-recorded by a Dutch native speaker) were spoken by a virtual agent to the participant during a virtual tour of eight scenes (e.g. a street, a forest, a bathroom). Sentences were either predictable or unpredictable based on the constraints of the verb, where the verb in the sentence could either be constrained towards a single item in the scene, making the sentence conclusion predictable (e.g. sentence 1 in Section 2.5), or unconstrained, related to multiple items in the scene, making the sentence unpredictable (e.g. sentence 2 in Section 2.5). In addition, the noun in the sentence could either refer to an item visible in the scene, confirming the listener’s prediction (congruent) or the referent could be absent from the scene, disconfirming the listener’s prediction (incongruent). The noun in the sentence was always a plausible continuation of the sentence, but manipulated congruency given that predictions were formed by combining the linguistic context of the sentence with the visual context of the scene.

We hypothesised that, in a critical time window between verb and noun onset, there would be an increased proportion of fixations towards the target object in the predictable but not the unpredictable condition (Heyselaar et al., 2020; Huizeling et al., 2022).

Based on the aforementioned literature, we also hypothesised that, in response to unpredictable relative to predictable nouns and prediction-congruent relative to -incongruent nouns, there would be a larger N400 response, a more positive anterior post-N400 effect, lower alpha and beta power, and higher theta power. These effects can be expected to result from the increase in processing required to suppress the predicted word and/or retrieve the unexpected/unpredicted word from long term memory. However, it should be noted that findings as to whether a late positivity is sensitive to mismatches between linguistic and visual information are mixed (Federmeier and Kutas, 2001; Willems et al., 2008b). In addition, it remains an open question as to what extent previous EEG findings actually generalise to more naturalistic and ecologically valid environments.

We additionally expected that, in the critical time window between verb onset and noun onset, there would be lower alpha and beta power in the predictable relative to unpredictable condition. Although there are a limited number of studies investigating the effect of constraining information on theta power, we hypothesised that we would either see no difference between predictable and unpredictable conditions (Li et al., 2017) or that there may be increased theta power in the predictable compared to unpredictable condition, given the increased retrieval of information from long term memory that is associated with making predictions.

Advancing technologies enable the on-line recording and co-registration of several data types at once. For example, EEG has been co-registered together with fMRI, MEG, eye-tracking and behavioural data, and eye-tracking has been co-registered with fMRI (Bonhage et al., 2015). However, these different data types are often analysed separately and only qualitatively compared. Prior research has used the EEG signal to predict RT data, as well as subsequent EEG effects (Alday & Kretzschmar, 2019; Lago et al., 2023; Maess et al., 2016). Here we quantitatively link EEG and eye-tracking data. First, we assessed to what extent the N400 amplitude and frequency power in response to the noun, which may quantify the ease of word processing, could be predicted from the proportion of anticipatory referent fixations prior to noun onset, which quantified noun predictability. We hypothesised that there would be a negative relationship between the proportion of anticipatory fixations prior to noun onset and the N400 amplitude in response to the noun. We additionally expected that anticipatory fixations may predict spectral power, consistent with expected effects of predictability on spectral power. Second, we investigated to what extent oscillatory activity after the constraining verb onset was associated with anticipatory fixations. We hypothesised that predictability-related modulations in alpha/beta and theta power would be associated with an increased proportion of target fixations. We additionally assessed to...
what extent N400 amplitude at noun onset could be predicted by spectral power at verb onset.

2. Methods

2.1. Participants

Thirty-eight right-handed native Dutch speakers took part in exchange for a standard fee. Three participants were excluded due to poor EEG data quality, two were excluded due to a technical fault and one was excluded due to poor performance on the comprehension questions and distracted behaviour during the experiment, suggesting they were not paying attention during the experiment. Thirty-two participants remained for the analysis (21 female, 10 male, 1 unreported gender, median age = 23 years, age range = 18–34 years, SD = 4). Participants with epilepsy, uncorrected visual or hearing impairments, colour-blindness, language impairments, dyslexia or developmental disorders were excluded from participation. The research was approved by Radboud University’s Faculty of Social Sciences (ethics application ECSW-2020-046) and complied with the Declaration of Helsinki.

2.2. Cave system

Stimuli were presented in VR using a cave automatic virtual environment (CAVE) system (Cruz-Neira et al., 1992). An example of the set-up can be seen in Fig. 1. A detailed description of the CAVE environment has previously been described in Eichert et al. (2018). The CAVE system consisted of three 255 × 330 cm projector screens (VISCON GmbH, Neurkirchen-Vluyn, Germany) arranged at right angles. Two vertically displaced, overlapping displays were back-projected onto each projector screen via a mirror by two projectors (F50, Barco N.V., Kortrijk, Belgium).

The experiment was programmed and run in Python through 3D VR software Vizard (Floating Client 5.4, WorldViz LLC, Santa Barbara, CA). Audio was presented through four surrounding speakers (Logitech, US) that were located in the four bottom corners of the CAVE, plus one centred at the bottom of the middle screen.

2.3. Eye- and head-tracking

Eye movements were recorded with specialised eye-tracking shutter glasses, which both tracked the participant’s eye movements and allowed them to see in 3D through a synchronised shutter mechanism for stereoscopic vision (SMI eye-tracking glasses 2 Wireless, SensoMotoric Instruments GmbH, Teltow, Germany). The interface for the eye-tracking calibration and data recording were on a tablet, which transmitted data wirelessly to the tracking software. A camera on the glasses measured 60 Hz binocular recordings with automatic parallax compensation. The accuracy of gaze tracking was 0.5° along each dimension according to manufacturer reports. The eye tracker’s latency of 60ms ± 10ms was corrected for in the analysis.

Head movements were tracked through six passive reflective markers that were placed on the left and right side of the frames of the eye-tracking glasses. Ten infrared cameras (Bonita 10, Vicon Motion Systems Ltd, UK) tracked the position of the reflective markers. Four of the infrared cameras were distributed below the screens at six were distributed above the screens. Head-tracking data were recorded to an accuracy of 0.5 mm with Tracker 3 software (Vicon Motion Systems Ltd, UK) at a sampling rate of 250 frames per second and were continuously combined with the eye-tracking data to determine where the participant was looking in 3D space.

The accuracy of the eye-tracking was determined with a two-step calibration procedure. The first step used the SMI software’s One Point Calibration procedure and assessed the accuracy of the eye-tracking alone (without the head-tracking). The participant was asked to look at a specific point in front of them (e.g. the corner of a piece of paper) and the experimenter corrected the gaze location in the software. The second step to the calibration procedure assessed the combined eye- and head-tracking, using an in-house calibration programme in VR, previously described by Eichert et al. (2018). Participants were presented with three spheres in 3D space, which each differed in position along the X, Y and Z axis. Participants were asked to look towards the centre of each sphere, during which the error between the estimated gaze position and the actual gaze position was corrected.

2.4. EEG acquisition

EEG data were continuously recorded with actiCAP EEG caps, which

Fig. 1. An example of the CAVE set up. Six of the ten infrared motion tracking cameras are visible, four above the three projector screens and two below. The scene displays the virtual agent in the street scene with six target objects (lamppost, basketball, flag, tree, letterbox, and wheelbarrow).
E. Huizeling et al.  
Neuropsychologia 191 (2023) 108730

contained 64 active Ag/AgCl electrodes, arranged in an equidistant montage. We used BrainAmp DC amplifiers (Brain Products, Gilching, Germany). The reference electrode was placed on the left mastoid. The ground electrode was placed on the forehead.

Four EOG electrodes recorded electric potentials caused by eye movements. Two electrodes were placed to the left of the left eye and to the right of the right eye to record horizontal eye movements. One electrode was placed above and one electrode was placed below the left eye to record vertical eye movements.

The data was recorded in BrainVision Recorder 1.2 (Brain Products, Gilching, Germany), at a sampling rate of 500 Hz and filtered online at 0.016–200 Hz. Impedance was kept below 10 kΩ (mean = 2.98, SD = 0.85) and measured with actiCAP 006 (Brain Products, Gilching, Germany).

2.5. Spoken sentence stimuli

Spoken sentence stimuli were adapted from Huizeling et al. (2022). Sentences consisted of 128 Dutch sentence sets that contained a subject-verb-object clause. All four sentences in a set were identical apart from the critical verb and the critical noun in the sentence. Sentences were predictable (50%) or unpredictable (50%) based on the verb constraints, where the verb in the sentence could either be related to a single object in the visual scene (predictive), or related to multiple objects in the scene (unpredictive). Verbs were matched for length (number of letters) and frequency, derived from SUBTLEX-NL (Keuleers et al., 2010). In 50% of sentences the noun referred to an object that was visible in the scene, congruent with the participant’s prediction, whereas the other 50% of sentences the noun referred to an object absent from the scene, incongruent with the participant’s prediction. The sentence always referred to a plausible object, but the constraints of the verb combined with the constraints of the visual scene determined congruency (see Fig. 1 for an example). Participants were presented with one of two sets of objects for any given scene, so that objects that were congruent/incongruent with the participant’s prediction were counterbalanced. In other words, referents perceived as congruent in one version of the experiment were perceived as incongruent in the second version of the experiment and vice versa. As a result, there were four versions of each sentence (predictable, object 1; unpredictable, object 1; predictable, object 2; unpredictable, object 2), as shown below (English translations written underneath, with critical verbs and nouns presented in bold font). The full set of sentence stimuli can be found in the supplementary material.

1. Mijn buurman is niet zo goed in het sturen van de kruivwagen.
   My neighbour is not very good at steering the wheelbarrow.

2. Mijn buurman is niet zo goed in het fixen van de kruivwagen.
   My neighbour is not very good at fixing the wheelbarrow.

3. Mijn buurman is niet zo goed in het sturen van de skelter.
   My neighbour is not very good at steering the go-kart.

4. Mijn buurman is niet zo goed in het fixen van de skelter.
   My neighbour is not very good at fixing the go-kart.

Sentences were recorded by a trained native Dutch speaker with the aim to sound as natural as possible. During the experiment, sentences appeared to the participant to be spoken by a virtual agent, who matched the recorded voice in apparent age and ethnicity, with lip synchronisation and eye gaze towards the participant. At the beginning of each scene the virtual agent began with an opening sentence about the scene.

2.6. Visual stimuli

Visual stimuli consisted of eight scenes (e.g., street, bathroom, restaurant) in which six critical objects were embedded. Each of the eight scenes were presented twice during the experiment, with different objects (and hence different sentences) embedded on each presentation. Each scene was presented once, followed by a reiteration of all the scenes in the reverse order (e.g. the experiment always started and ended with the street scene). The order of the scenes remained consistent across experiments, but the order of the sentence-object sets was counterbalanced. Note that, due to counterbalancing objects across the condition of congruency (see Section 2.2, Spoken Stimuli), there were in fact four different object sets that were associated with each scene, but each participant only ever saw two of these sets.

For example, for 50% of participants the first street scene contained sentence-object set A (lamppost/traffic light, basketball/volleyball, flag/table cloth, tree/bush, letterbox/dustbin, and wheelbarrow/go-kart) and for 50% of participants the first street scene contained object set B (lolly/donut, hula hoop/marbles, traffic barrier/firework, umbrella/garden chair, balls/marbles, and bucket/watering can).

Objects were placed so as to appear as natural as possible within the scene in regards to scale and position. The virtual agent was positioned in the scene so as to be easy to locate, often towards the centre of the scene. Visual stimuli, including the scenes, the virtual agent and approximately half of the objects were the same as those used in (Huizeling et al., 2022).

In order to counterbalance the objects that would confirm vs disconfirm participants’ predictions, for each sentence set there were two possible objects that could be displayed. For example, the scene presented in Fig. 1 could either display the wheelbarrow (as shown) or a go-kart. The former would mean that sentence 1 above (in Section 2.5) confirms the participant’s prediction but sentence 3 disconfirms the participant’s prediction, and the latter would mean that sentence 3 above confirms the participant’s prediction but sentence 1 disconfirms the participant’s prediction.

2.7. Procedure

Participants listened to sentences spoken by a virtual agent during a virtual tour of eight scenes (e.g., an office, a living room, a canteen). The agent discussed her relation to each scene while participants’ eye movements and EEG were continuously recorded. Participants were instructed that they would be taken on a tour through the virtual agent’s life, that they only needed to listen to the virtual agent but that they would be asked questions about what she said at the end of the experiment to check that they were paying attention.

Sentence sets were separated into eight lists (4 sentence types × 2 object sets) that participants were randomly assigned to, so that no participant heard more than one sentence from a set (see Section 2.5 and Section 2.6 for details).

During the experiment participants were seated on a chair in the centre of the CAVE, with the EEG and eye-tracking equipment placed on a table behind them. Participants were instructed that they could make small, gentle head movements, but they should not turn their head fully to the right or left, up or down. The experiment was divided into four blocks of four scenes, allowing the participant opportunities for self-paced breaks. In between each block the experimenter checked the calibration of the eye tracker using the 3D calibration step (see Section 2.6 Eye- and head-tracking).

After the experiment was complete, participants completed two questionnaires on LimeSurvey. The “Object questionnaire” presented participants with a list of all the objects that had been presented during the experiment and, for each object, participants selected either “Ja” (yes) or “Nee” (no) to indicate whether the virtual agent had referred to the object during the experiment. The “Verb questionnaire” presented participants with the list of critical verbs that the virtual agent had
spoken within a sentence during the experiment (both the word form spoken in the experiment, and the full verb). Participants selected “Ja” (yes) or “Nee” (no) to indicate whether or not they knew the meaning of the verb. Data are available from the Max Planck Institute for Psycholinguistics’ Language Archive (https://hdl.handle.net/1839/607d53a-d9a81-4891-856c-8bfca9f99a8b).

2.8. Data analysis

2.8.1. Eye-tracking

Eye-tracking data were analysed in R (version 4.1.2; R Core Team, 2021). Trials were time locked to 60ms after sentence onset to account for the eye tracker latency. To account for eye blinks or loss of eye tracker connectivity, samples were removed if eye-tracking coordinates along all three dimensions (X-Y-Z) remained the same for more than two samples. Trials were excluded from further analysis if >25% of samples were removed from within the critical time window. There was a maximum exclusion of nine trials per participant (mean = 2.72, SD = 2.22). Eye gaze on an object was considered a fixation if it exceeded 100ms.

In line with our previous work and with recommendations of analysing VWP data (Porretta et al., 2018) we analysed the data with generalized additive mixed effects models (GAMMs) using the bam function from mgcv (version 1.8-26; Wood, 2017) and using isodug (version 2.3; Van Rij, Wieling, Baayen and Van Rijn, 2017) to interpret results. GAMMs extend the linear mixed-effects regression framework to include smooth curves and so can detect both linear and non-linear effects. Detailed discussions of the advantages of using GAMMs can be found in the previous literature (Porretta et al., 2018; Van Rij, Hendriks, Van Rijn, Baayen and Wood, 2019; Wieling, 2018; Winter and Wieling, 2016). In sum, GAMMs allowed us to model non-linear effects of continuous variables, which enabled us to enter time as a continuous predictor in our model to investigate whether target fixations changed dependent on time and condition. Moreover, as GAMMs can model both linear and nonlinear effects we were not required to make assumptions about the linearity of our data.

Data were analysed during a critical window of 200ms after verb onset until the mean noun onset to account for the time it takes to program an eye-movement (Rayner et al., 1983). Binomial responses of whether the target object was fixated or not were entered into the model as a dependent variable, applying a logit link function. Sentence Predictability (predictable/unpredictable) was entered into the model as a parametric effect along with factor smooth interactions of Time \times Predictability, Time \times Sentence and Time \times Subject. Predictability was coded with a deviation contrast-coding scheme (with contr. sum), which compares the mean proportion of fixations for each level of predictability with the overall mean across levels. To avoid overfitting, the parameter k (which limits the number of basis functions used to fit the model) was limited to five. To remain consistent with (Huizeling et al., 2022), Maximum Likelihood estimation was selected to smooth parameter estimates (Wieling, 2018). Segments of time with significant differences between conditions were estimated with the plot.diff function. Analysis scripts for modelling eye-tracking and EEG data are available from the Max Planck Institute for Psycholinguistics’ Language Archive (https://hdl.handle.net/1839/607d53a-9a81-4891-856c-8bfca9f99a8b).

2.8.2. EEG

2.8.2.1. Preprocessing

Data were analysed in MATLAB toolbox fieldtrip-2020,831 (Oostenveld et al., 2011). Data were band pass filtered between 0.1 and 35 Hz, using a forward-backward zero-phase 4th order Butterworth filter with a Hamming window, and re-referenced to the average of the left and right mastoids. For the optimal detection of eye artifacts we followed the recommendations for free-viewing paradigms outlined in Dimigen (2020). Specifically, the independent component analysis (ICA) training data (henceforth called ICA data) were band-pass filtered between 2 and 100 Hz using a forward-backward zero-phase finite impulse response window sync filter with a Hamming window. The ICA data was demeaned and line noise was removed using a discrete Fourier transform.

Both the ICA data and “true” data were then epoched from -1000-2000ms relative to verb and noun onset. Note that this meant that the baseline window of the noun often overlapped with the verb and thus differed between conditions. This was controlled for in the analysis by including the baseline and an interaction between baseline and condition as predictors in the model (see Section 2.8 ERPs and Spectral analysis). However, it meant that the ICA assumption of independent samples was violated. On visual inspection of the ICs, this did not appear to affect the performance of the ICA. Trials were then visually inspected and noisy trials were removed prior to running ICA (with fieldtrip’s runica). Components were visually inspected and those resembling artifacts caused by eye blinks, horizontal eye movements and spike potentials were then removed from the main data. Noisy sensors were interpolated with the average signal of neighbouring sensors.

2.8.2.2. ERPs

For the analysis of the N400 in response to the critical noun, the EEG signal was averaged over time, from 300 to 500ms, and over space across centroparietal sensors, plotted in Fig. 4. Averaged data were entered into a linear mixed effects model, using lmer from lme4 (Bates et al., 2015), with baseline (centred), condition (predictable vs unpredictable/congruent vs incongruent) and a baseline × condition interaction as covariates, and random intercepts for subject and item. The baseline was defined as the average amplitude in the 100ms prior to noun onset and was included in the model to control for fluctuations in pre-stimulus EEG amplitude (Allday, 2019). A model comparison procedure revealed no significant difference between a model containing random slopes of condition and random intercepts for subject and item ($\chi^2 = 6.10, df = 4, p > .10$). The model was therefore simplified to include only random intercepts in order to maintain parsimony and computational efficiency (Bates, 2019; Matuschek et al., 2017). Separate models were used to investigate the effect of congruency (congruent vs incongruent) and the effect of predictability (predictable vs unpredictable). The degrees of freedom (df) of fixed effects were computed with Satterthwaite approximation using the lmerTest package (version 0.9–40; Kuznetsova et al., 2017).

For the analysis of the post-N400 time window, time-locked to the critical noun, a time window of 700–1700ms was selected to avoid overlap with the N400 itself. Data were down-sampled to 125 Hz. The paradigm used in the current study was different to those used in most previous studies that investigate the post-N400 time window and we had no clear hypothesis about the specific latency of expected effects. Data were therefore analysed with GAMMs (k limited to 10), allowing us to include time as a continuous predictor in the models (see Section 2.8 Data Analysis, Eye-tracking). GAMMs have been used to model EEG data in past research (Hendrix et al., 2017; Lago et al., 2023; Tremblay and Newman, 2015). Previous investigations of the post-N400 have found differential anterior and posterior effects (DeLong et al., 2014; Fermenier et al., 2007; Quante et al., 2018; Thornhill and Van Petten, 2012; Van Petten and Luka, 2012). Data were averaged over sensors encompassed in two regions of interest (ROI), including an anterior and a posterior ROI (see selected electrodes for each ROI plotted in Fig. 5). In addition to time (in steps of 6ms and centred) and ROI, condition, baseline (centred), and an interaction between condition and ROI were entered into the model as parametric effects, as well as smooth terms for time by condition and time by condition aggregated with ROI. Random smooths were entered for subject and item. Separate models were fit to investigate the effect of congruency (congruent vs incongruent) and the effect of predictability (predictable vs unpredictable). For each model, condition was coded with a deviation contrast-coding scheme (with...
2.8.2.3. Spectral analysis. Time frequency analysis was performed from -1000 - 1500ms relative to verb and noun onset, from 2 to 30 Hz for every 1 Hz, with a sliding window moving in stages of 50ms with four cycles per time window and applying a Hann taper (as specified by “Hanning” in fieldtrip).

A time window of 0–1000ms relative to verb/noun onset was selected for further investigation, as well as theta (4–6 Hz), alpha (7–11 Hz) and beta (14–30 Hz) frequency bands, within which frequency power was averaged for further analysis. The specific alpha range was selected based on visual inspection of Figure SM1, which displays a time frequency representation (TFR) averaged across all conditions and all electrodes (Luck and Gaselin, 2017). As no specific frequency effects are visible in the theta or beta ranges in Figure SM1, standard theta and beta ranges of 4–6 Hz and 14–30 Hz, respectively, were selected, while avoiding overlap with the selected alpha band.

As there was no clear hypothesis about the latency at which effects may be observed in theta and alpha frequencies, we again kept time as a continuous predictor (in steps of 50ms) and analysed the data with GAMMs. Data were averaged across sensors within two ROIs, an anterior and posterior ROI (see Fig. 8) and log transformed for the analysis. Posterior and anterior sensors were selected as ROIs in accordance with previous effects of context constraints on pre-stimulus alpha power recorded with EEG (Rommers et al., 2017). In addition to time (centred) and ROI, condition and a condition × ROI interaction were entered into the model as parametric effects. Smooth terms for time by condition and time by condition aggregated with ROI were added to the model. Random smooths were entered for subject and item. Separate models were used to investigate the effect of congruency (congruent vs incongruent) and the effect of predictability (predictable vs unpredictable).

The baseline was not entered into models analysing oscillatory power, as the time-frequency decomposition does not suffer from the slow drifts in EEG data that is present in ERPs.

2.8.3. Predicting N400 amplitude and frequency power from anticipatory fixations

We hypothesised that the prediction of the referent before noun onset would influence the ease of noun processing and that this would be reflected in the EEG data. The proportion of fixations towards the referent prior to noun onset was taken as a metric of prediction. This differs from using the condition of predictability as a (binary) predictor, as there may be variability within conditions and across participants as to whether the referent was predicted or not.

To this end, N400 amplitude and log frequency power (alpha and theta, 0–1000ms) were exported from MATLAB, read into R with R. matlab (Bengtsson, 2017) and then entered into three separate linear mixed effects model (lmer from lme4) as dependent variables, with the time (number of samples) spent fixating the target as a predictor variable and random intercepts for subject and item. Random slopes of condition for subject and item were included in the frequency models but omitted from the N400 model because the resultant fit was singular (Bates, 2019). Baseline amplitude and ROI (anterior/posterior) were entered as additional predictor variables for the N400 and frequency models respectively. A model comparison procedure showed that adding an interaction between baseline amplitude and target fixations did not improve the model fit ($\chi^2 = 2.36$, df = 1, $p > .10$). Similarly, whereas including ROI as a predictor improved the model fit for both theta ($\chi^2 = 228.60$, df = 1, $p < .001$) and alpha ($\chi^2 = 26.49$, df = 1, $p < .001$) models, adding an interaction between ROI and target fixations did not improve the model fit for either theta ($\chi^2 = 1.28$, df = 1, $p > .10$) or alpha ($\chi^2 = 0.03$, df = 1, $p > .10$). Nevertheless, we report the models containing the interaction in Table 8 in Section 3.3, as the theta model without the interaction failed to converge. This did not change the overall pattern of results and made only minor differences to the models’ estimates.

The time spent fixating the target in the time window between 490ms after the verb onset until mean noun onset was selected as a metric for predictability, consistent with the time window in which a significant effect of predictability on target fixations was found (see Section 3.1). Trials were restricted to those in which the referent was visible in the scene, confirming the participant’s prediction, rather than those in which the referent was not present in the scene, as we were only interested in effects of noun predictability and not congruence of the referent with the prediction.

2.8.4. Predicting N400 amplitude from frequency power

We hypothesised that frequency power at verb onset would be predictive of N400 amplitude at noun onset. Frequency power (theta, 4–6 Hz; alpha 7–11 Hz) averaged over time (0–1000ms relative to verb onset) and electrodes within two ROIs (anterior and posterior; see Fig. 5) was centred and entered as a predictor in two linear mixed effects models with additional predictors of baseline N400 amplitude (centred), condition (predictable-congruent, unpredictable-congruent, predictable-incongruent, and unpredictable-incongruent) and condition × anterior frequency power and condition × posterior frequency power interactions. The models contained random intercepts for sentence and subject. Models containing additional random slopes did not converge. A model comparison procedure revealed no significant difference between models containing only random intercepts and models containing random slopes of frequency power for subject and item (p > .10). Separate models were fit for alpha and theta power. There was some collinearity between frequency power in the two ROIs (the generalized variance-inflation factors, GVIIFs’ (1/(2*Df)), for the two respective interaction terms were alpha: 1.79 and 1.50; theta: 2.19 and 2.23) and so caution should be taken when making inferences about the topography of effects.

2.8.5. Predicting anticipatory fixations from frequency power

For anticipatory fixations to take place, the listener must first combine information from the constraining verb with the constraints of the visual scene. Anticipatory processing may therefore be reflected in the brain signal prior to fixations towards the predicted item. We therefore tested whether anticipatory fixations could be predicted by frequency power after verb onset, with the length of time spent fixating the referent between 490ms relative to verb onset until noun onset as the dependent variable.

Frequency power (theta, 4–6 Hz; alpha 7–11 Hz) averaged over time (0–1000ms relative to verb onset) and electrodes within two ROIs (anterior and posterior; see Fig. 8) was a predictor in the models. Due to the collinearity between the data within the two ROIs, fixation data were modelled as a function of frequency power in each ROI in separate models. Alpha and theta frequency bands were additionally run as separate models. Multiple comparisons of two tests for the two separate ROIs were corrected for with Bonferroni correction, adjusting the significance threshold to $p < .025$.

Due to the large number of trials in which the target was not fixated, there was a disproportionately large number of zeros in the data, which could not be accommodated by distributions typically used to model count data, such as Poisson or negative binomial distributions. The pattern of fixations can be separated into a) the decision to fixate on the target object and b) the length of time (number of samples) the item is fixated for during the critical time window. Such differences could reflect different underlying cognitive processes. We therefore implemented a hurdle model to model fixations. A hurdle model fits the model in two stages, thereby accounting for the large number of zeros. The first part of the model fits the probability of the target being fixated. The second part of the model describes the length of time (number of samples) the object was fixated, given that it was fixated, with a Poisson distribution.

To allow for modelling a nested random effects design, in order to
control for items and subjects, and for continuity across analyses, data were modelled using the \textit{gam} function from the \textit{mgcv} package, with a \textit{ziplss} family. For both stages of each hurdle model, average frequency power was entered as a parametric predictor and as a smooth term. Random smooths were entered for subject and item. Here, GAMMs allowed the number of fixations to vary non-linearly as a function of frequency power, but could also detect linear effects if present. GAMMs have previously been used to co-register EEG and eye-tracking data (Kretzschmar et al., 2015; Nikolaev et al., 2016; Van Humbeck, Meghanathan, Wagemans, van Leeuwen and Nikolaev, 2018).

3. Results

All participants achieved over 71% accuracy on the Object questionnaire (mean = 86.69%, SD = 6.43%), suggesting that all participants were attentive. For each verb, we calculated the percentage of participants who knew the meaning of the verb. Each individual verb was known by an average of 98.62% participants (SD = 5.71). No further analysis was conducted on the questionnaire data.

3.1. Eye gaze

Fig. 2 presents the proportion of fixations towards the target, distractors and virtual agent while listening to predictable and unpredictable sentences.

The model (see Table 1) revealed a parametric effect of condition, with a greater proportion of target fixations in the predictable compared to unpredictable condition. There was a significant smooth for time for predictable but not unpredictable sentences, which resulted from an increase in fixations over time in the predictable but not the unpredictable condition (see smooth plotted in Fig. 3).

Model estimated difference curves are presented in Fig. 3. As the model estimated the effect to be linear, it estimated the proportion of fixations to be greater in the unpredictable relative to predictable condition from 480ms after the verb onset until 800ms after verb onset.

3.2. EEG

3.2.1. N400

ERPs in response to noun onset, averaged over centroparietal electrodes, are presented for each condition in Fig. 4. The waveform of a single centroparietal electrode is presented in Figure SM2 in the supplementary material. To investigate effects of predictability and congruence on the N400 amplitude, two linear mixed effects models were conducted on the average data from a group of centroparietal electrodes between 300 and 500ms (see Fig. 4 panel A for a schematic of the selected electrodes). The model (see Table 3) revealed a significant effect of congruency on the N400 amplitude, in which the N400 time-locked to noun onset was larger for prediction-incongruent compared to congruent nouns. However, contrary to our hypotheses, there was no significant effect of predictability on N400 amplitude (see Table 2).

3.2.2. Post-N400

A later, post-N400, component is thought to reflect ongoing processing after the word has been perceived, for example, through reanalysis or updating of the sentence interpretation, or integrating new semantic information to the prior context. Based on the aforementioned literature, we hypothesised that there would be a more positive post-N400 in response to unpredictable compared to predictable nouns and in response to incongruent relative to congruent nouns. To investigate amplitude modulations in a post-N400 time window, we used GAMMs to model the change in amplitude over time 700–1000ms after noun onset, in a posterior and an anterior ROI. ERP waveforms for the two ROIs are presented in Fig. 5 and the model summaries can be found in Table 4.

There was a significant parametric effect of predictability on post-N400 amplitude, as well as ROI and the baseline amplitude. Model estimated post-N400 amplitude was more positive in the predictable compared to unpredictable condition, contrary to our hypotheses (see Figure SM3 in the supplementary material for time windows of significant differences). There was a significant interaction between predictability and ROI. Inspection of the smooth terms revealed that the change in amplitude during the post-N400 time window reversed in direction for anterior and posterior ROIs but was qualitatively similar across predictable and unpredictable conditions (see Fig. 6).

We found a significant parametric effect of congruency on the post-N400 amplitude in response to the noun, as well as effects of ROI and the baseline amplitude. Consistent with our hypotheses, model estimated post-N400 amplitude was overall more positive in the incongruent compared to congruent condition. There was a significant interaction between congruency and ROI. The smooth terms presented in Fig. 7 revealed that the change in amplitude over time predominantly differed across conditions in the posterior ROI, where there was a decrease in amplitude over time in the congruent but not the incongruent condition (also shown in the model estimated difference curves presented in Figure SM4 in the supplementary material).

In summary, we found effects of both predictability and congruence on post-N400 components, where amplitude was overall greater in the predictable and incongruent conditions relative to the unpredictable and congruent conditions, respectively. The effect of time on EEG amplitude was qualitatively similar across predictable and unpredictable conditions. In contrast, an effect of congruency over time was predominantly seen in the posterior ROI, where amplitude further decreased over time in the congruent but not the incongruent condition.

3.2.3. Frequency

3.2.3.1. Verbs. TFRs and topographical plots presenting frequency power in the time window following verb onset are presented in Fig. 8. To investigate theta power modulations in response to (un)predictive verbs, we used GAMMs to model the change in theta power over time 0–1000ms after critical verb onset in a posterior and an anterior ROI. Effects in theta power in response to constraining information have not often been reported in the previous literature. In one study, Li et al. (2017) reported no significant difference in theta power in response to constraining and unconstraining verbs in written Chinese sentences.

We found a significant parametric effect of verb predictivity on theta power after verb onset, where theta power was higher in response to predictive relative to unpredictable verbs. There was a significant effect of ROI, with higher theta power in the anterior relative to posterior ROI (see also TFR in Fig. 8 panel A), but no significant interaction between ROI and condition.

Significant smooth terms show a linear (edf is close to 1; see Table 5) change in theta power over time for predictive verbs in the anterior ROI. Theta power was greater in response to predictive compared to unpredictable verbs from 650ms (see differences between predictive and unpredictable smooth terms presented in Fig. 9 panel A and B). There was also a significant smooth for time for the unpredictable verbs in the anterior ROI, however, this was close to the threshold of significance ($p = .043$). There were no other significant smooths for time.

It was hypothesised that there would be lower alpha and beta power in response to predictive compared to unpredictable verbs (Gastaldon et al., 2020; Leon-Cabrera et al., 2022; Li et al., 2017; Molinaro et al., 2017; Piai et al., 2014; Rommers et al., 2017; Roos and Piai, 2020; Terporten et al., 2019; Wang et al., 2018). The model summary for alpha power can be found in Table 5. Only tentative effects of verb predictivity were found in beta power. Results for beta power can be found in the supplementary material (see pable SM1).

There was a significant parametric effect of verb predictivity on alpha power after verb onset, as well as a significant effect of ROI and a significant interaction between ROI and condition. Contrary to our

Fig. 3. Model estimated smooths and difference curve for target fixations: Model estimated smooths for the proportion of fixations in predictable (red) and unpredictable (teal) sentences (panel A) and the difference between the model-estimated smooth splines of the predictable and unpredictable conditions (panel B). Red dashed lines mark windows of significant differences. Time is relative to verb onset.

Fig. 4. ERP amplitudes (μV) in response to noun onset averaged over centroparietal sensors. A baseline of 100ms prior to the noun onset was subtracted from the amplitude. Topographical plots display the difference in amplitude (congruent – incongruent left, predictable – unpredictable right) averaged between 300 and 500ms after noun onset. Time (s) is relative to noun onset. The grey shaded area highlights the time segment that was averaged over and entered into the linear model. ***$p < .01$, ns $p > .10$.

Fig. 6. Model estimated smooths for amplitude in response to predictable and unpredictable nouns in anterior (panel A) and posterior (panel B) ROIs. Time is relative to noun onset.

Fig. 7. Noun congruency model estimated smooths for amplitude in response to congruent and incongruent nouns in anterior (panel C) and posterior (panel D) ROIs. Time is relative to noun onset.
for time for this condition (see Table 5). There were no other significant
information from long term memory.
2008a), reflecting an increased effort to retrieve lexical and semantic
and Hagoort, 2015; Li et al., 2017; Rommers et al., 2017; Willems et al.,
relative to predictable and congruent nouns were expected (Bastiaansen
power in the time window following noun onset are presented in Fig. 10.
0 to 880ms in the posterior ROI and from 250 to 860ms in the
in the anterior ROI. There were no other significant smooths for time (p > .10).
Supporting our hypotheses, there was a significant parametric effect of
congruency on theta power, where theta power was higher in
in response to incongruent compared to congruent nouns (see Table 7).
There was a significant effect of ROI, with higher theta power in the
compared to posterior ROI, and a significant interaction be-
tween condition and ROI.
Theta power significantly changed over time in the posterior ROI in
response to incongruent nouns only (see smooth terms in Table 7). In
both posterior and anterior ROIs theta was higher in the incongruent
relative to congruent nouns from around 400ms (340ms and 420ms for
and anterior ROIs respectively), as can be seen in the model
estimated difference curves presented in Fig. 12 panel A–B. Differences
peaked at around 600ms after noun onset.
We expected lower alpha and beta power for incongruent compared
to congruent nouns (Rommers et al., 2017; Wang et al., 2012; Willems
et al., 2008a). On the other hand, we had no clear evidence to expect a
difference in alpha or beta power between predictable and unpre-
table nouns (Rommers and Federmeier, 2018; Terporten et al., 2019).
Only tentative effects of noun predictability and congruence were found
in beta power. Results for beta power can be found in the supplementary
material (see Tables SM2 and SM3).
There was a significant parametric effect of noun predictability and
ROI on alpha power in response to noun onset, but no interaction be-
tween predictability and ROI (see Table 6). Alpha power was lower in
response to predictable compared to unpredictable nouns, around
200–720ms relative to noun onset (see model estimated difference
curves in Fig. 11 panels C and D).
There was a significant smooth for time for unpredictable nouns
when collapsed across ROIs, suggesting that alpha power changed over
time in this condition. However, when separated across ROIs
the smooths for time did not reach significance (p = .089).
There were significant parametric effects of congruence and ROI on
alpha power, but no significant interaction between condition and ROI.
Alpha power was higher in the incongruent relative to congruent nouns
from 350 to 1000ms in the anterior ROI and between 410 and 1000ms in
the posterior ROI (see model estimated differences in Fig. 12). The
smooth for time for alpha power in the congruent condition did not
reach significance (p = .057). There were no other significant smooths
for time (p > .10).
Summary of frequency results.
In summary, effects of verb predictivity and noun predictability were
observed most robustly in theta and alpha power. Higher theta and
alpha power were both seen either after hearing a predictable verb
(relative to unpredictable) or an unpredictable or incongruent noun
(relative to predictable or incongruent respectively).

3.3.1. Predicting N400 amplitude from anticipatory fixations
We hypothesised that the prediction of the referent before noun
onset would influence the ease of processing once the noun was
perceived. In the analysis of the eye-tracking data (see Section 3.1), an
effect of predictability on target fixations was found from 490ms after
the verb onset. We therefore investigated to what extent the proportion
of fixations from 490ms post-verb onset until mean noun onset could

3.2.3.2. Nouns. TFRs and topographical plots presenting frequency
power in the time window following noun onset are presented in Fig. 10.
Greater theta responses to both unpredictable and incongruent nouns
relative to predictable and congruent nouns were expected (Bastiaansen
and Hagoort, 2015; Li et al., 2017; Rommers et al., 2017; Willems et al.,
2008a), reflecting an increased effort to retrieve lexical and semantic
information from long term memory.
There was a significant parametric effect of predictability and ROI on
theta power after noun onset, where theta power was lower in response
to predictable compared to unpredictable nouns. There was no signifi-
cant interaction between condition and ROI.
There was a significant smooth for time for unpredictable nouns,
which stemmed from the posterior ROI (see Table 6). Accordingly, a
peak in theta power in response to unpredictable nouns can be seen in
the posterior ROI’s TFR in Fig. 10 and the smooths in Fig. 11 panel F,
peaking at around 600–700ms after noun onset. From the model esti-
mated difference curves presented in Fig. 11 panel A–B, it can be seen
that theta was greater for unpredictable relative to predictable nouns
from 220 to 880ms in the posterior ROI and from 250 to 860ms in the
anterior ROI. There were no other significant smooths for time (p > .10).

predict N400 amplitude in response to the noun. As we were only interested in sentence predictability and not congruence, for this analysis we only included trials where the referent was visible in the scene, confirming the participant’s prediction. This question was investigated with a linear mixed effects model with N400 amplitude as a dependent variable, the proportion of target fixations and baseline EEG amplitude as predictor variables (see Methods Section 2.8 for details). Target fixations did not significantly predict N400 amplitude (\(B = 1.32, SE = 0.86, t = 1.54, p > .10\)). The model summary can be found in the supplementary material (Table SM4).

3.3.2. Predicting N400 amplitude from frequency power

The processing of the constraining information at verb onset was expected to influence the ease of subsequent noun processing. We therefore expected frequency (theta/alpha) power at verb onset to

Red dashed lines mark windows of significant differences.
predict the N400 amplitude at noun onset. N400 amplitude was entered into two linear mixed effects models as a dependent variable, with anterior frequency power, posterior frequency power, baseline amplitude, condition, a condition × anterior frequency power interaction and a condition × posterior frequency power interaction as predictors (see Methods Section 2.8 for details). Here we focused only on theta and alpha frequencies, as it was in these frequency bands that we predominantly observed effects of noun predictability (see Results, Frequency, Section 3.2.3).

The model summaries are presented in Tables 8 and 9. There was no main effect of theta power on N400 amplitude (p > .05). However, there was a significant interaction between theta power and condition, in both predictable congruent and predictable incongruent conditions in the anterior ROI. An estimate of 0.24 for the predictable congruent condition interaction (see Table 8) suggests that, relative to the average of all other conditions, the N400 amplitude was more positive with increased theta power. In other words, when the noun was predictable and congruent with the prediction, the N400 amplitude at noun onset decreased with increased theta power after verb onset. An estimate of −0.17 suggests that the opposite pattern was true for the predictable incongruent condition, where increased anterior theta power at verb onset resulted in a more negative (larger) N400 amplitude at noun onset.

There was a main effect of alpha power on N400 amplitude for the unpredictable congruent condition and the predictable incongruent condition. There was additionally a significant interaction between condition and alpha power in the anterior ROI, where N400 amplitude at noun onset decreased (became more positive) with increased alpha power at verb onset when the noun was predictable and congruent, as shown by the estimate of 0.15 (see Table 9).

3.3.3. Predicting frequency power from anticipatory fixations

We investigated to what extent the proportion of fixations before noun onset could predict log frequency power in the 0–1000ms after noun onset. To this end, log theta power and log alpha power were entered into two linear mixed effects models as dependent variables, with target fixations, ROI and a target fixations interacts with ROI as predictors (see Methods Section 2.8 for details).

The proportion of fixations prior to noun onset was negatively associated with both theta and alpha power in the time period after the noun onset (see Tables 10 and 11, respectively for model summaries). A greater proportion of anticipatory target fixations was therefore associated with a weaker theta/alpha increase at noun onset. There was a significant effect of ROI, but no interaction between ROI and target fixations.

3.3.4. Predicting anticipatory fixations from frequency power

We hypothesised that oscillatory activity time-locked to the verb onset would predict anticipatory target fixations. We therefore investigated the extent that spectral power, averaged over 0–1000ms after verb onset, could predict the proportion of fixations in the time window from 490ms after verb onset until noun onset.

Due to the large number of zeros in the data, hurdle GAMM models were used (see Methods, Data Analysis Section 2.8). The proportion of target fixations was entered into the model as a dependent variable, with frequency power as a predictor and subject and sentence as random smooths. Data from anterior and posterior ROIs, and for alpha and theta frequencies, were entered into separate models. Model summaries are presented in Tables 12 and 13.

3.3.4.1. Theta anterior ROI. The zero part of the model tested the extent to which each variable predicted the binary outcome of whether or not the target object was fixated during the specified time window. There was no parametric effect of theta power and no significant smooth for theta power. These findings demonstrate that frontal theta power is not a good predictor of whether the participant will fixate on the target.
The non-zero part of the model tested the extent to which theta power predicted the total fixation time during the selected time window, conditional on having fixated the object. There was no parametric effect of theta power but there was a significant smooth for theta power.

3.3.4.2. Theta posterior ROI. There was no parametric effect of posterior theta power on whether or not the target object was fixated during the critical window. The smooth for theta power in the zero part of the model did not reach significance after Bonferroni correction for multiple tests (p = .044 uncorrected). There was, however, a significant parametric effect of theta power on the duration of fixations given the target was fixated and a significant smooth for posterior theta power on the total duration of fixations during the critical window.

For abbreviations, see legend of Table 5.

3.3.4.3. Alpha anterior ROI. Neither the zero nor non-zero parts of the model revealed significant parametric effects nor any significant smooth for anterior alpha power.

3.3.4.4. Alpha posterior ROI. In the zero part of the model, there was no significant parametric effect of posterior alpha power on the number of fixations and no significant smooth for alpha power. In the non-zero part of the model, there was no significant parametric effect of alpha power on total fixation duration, but a significant smooth for posterior alpha power.

3.3.5. Summary of combined analysis results
Anticipatory target fixations predicted spectral power (alpha and theta) but not N400 amplitude after noun onset. Spectral power after verb onset did not predict the binary outcome of whether or not the target was fixated prior to noun onset. However, posterior theta power after verb onset predicted the amount of time spent fixating on the target prior to noun onset given the target was fixated to begin with. No such relationship was found with alpha power. Theta and alpha power at verb onset interacted with condition when predicting N400 amplitude at noun onset, where an increase in anterior alpha and theta was associated with a smaller N400 in the predictable congruent condition, but there was a larger N400 in the predictable incongruent condition with increased anterior theta power.

4. Discussion
We tested the extent to which EEG and eye-tracking data could be simultaneously recorded and combined to investigate predictive processing of upcoming speech in naturalistic environments, in VR. Advancements in recording and data processing techniques mean that it is now possible to record EEG during free-viewing paradigms, uncovering a wide range of possibilities to study important theoretical questions in naturalistic environments in the lab. When studying prediction during spoken language comprehension, although eye gaze allows us to see whether a prediction can be made before the verbal onset of the referent, it is not possible to determine whether a reduction in the proportion of fixations is due to a shift in visual attention or an actual change in the listener’s prediction. On the other hand, although the EEG signal at the onset of a spoken word provides an indication of the ease of word processing the moment it is perceived, we are not yet able to use the EEG signal alone to determine whether a noun was predicted or not. These two methods therefore provide complementary information that can be combined to answer important theoretical research questions (Knoeferle, 2015). Here we present a proof-of-principle investigation to test whether these methods can indeed be successfully combined to study the prediction of speech in naturalistic environments.

In summary, we replicated increased anticipatory fixations towards a referent when the verb in the sentence was predictive compared to unpredictive. We also found that the predictiveness of the verb and predictability of the noun were related to modulations in theta (4–6 Hz) and alpha (7–11 Hz) frequency bands at verb and noun onsets. Only tentative modulations were found in the beta frequency band (14–30 Hz). Increased theta power, arguably reflecting increased processing, occurred either at the constraining verb onset in predictable sentences or at noun onset in unpredictable sentences. Accordingly, anterior theta and alpha power after verb onset predicted subsequent N400 amplitude at the noun onset. Although spectral power (alpha and theta) at verb onset did not predict whether or not the target was fixated prior to noun onset, posterior theta power at verb onset did predict the amount of time spent fixating on the target prior to noun onset given the target was fixated to begin with. No such relationship was found with alpha power. The proportion of anticipatory fixations was found to predict theta and alpha power after the noun onset, possibly reflecting the need for fewer processing resources to process a word that has been predicted. The predictability of the noun was also associated with modulations in post-N400 ERP amplitudes, but not with the N400 amplitude itself, contrasting with the previous literature. Nouns congruent with the prediction were, however, associated with a smaller N400 amplitude relative to incongruent nouns. Noun congruence was additionally associated with modulations in the post-N400 ERP amplitude, as well as in alpha and theta band power. Below we discuss these results, and their theoretical and methodological implications, in more detail.

4.1. Noun predictability
We replicated the finding of increased anticipatory target fixations prior to noun onset in the predictable relative to the unpredictable...
Fig. 11. Noun predictability modulated frequency power difference curves (panels A–D) and model estimated smooths (panels E–H): The difference between the model-estimated smooth splines of the predictive and unpredictive conditions for log theta (panels A–B) and alpha (panels C–D) power, and model estimated smooths for log theta (panels E and F) and alpha (panels G and H) power in anterior (panels A, C, E and G) and posterior (panels B, D, F and H) ROIs in the 1000 ms following noun onset. Red dashed lines mark windows of significant differences.
condition in a naturalistic virtual environment (Heyselaar et al., 2020; Huizeling et al., 2022). Fixations towards the target increased 480ms after verb onset to a proportion of ~0.12, which is consistent with Huizeling et al. (2022) and Heyselaar et al. (2020), where anticipatory fixations were found to increase at around 400ms after the constraining verb onset to a proportion of ~0.15. Importantly, these findings confirm that the referent was predicted before noun onset.

Both theta and alpha power were found to be greater in response to unpredictable compared to predictable nouns. Additionally, an increase in the proportion of anticipatory target fixations prior to the noun

**Fig. 12.** Noun congruence modulated frequency power difference curves: The difference between the model-estimated smooth splines of the predictive and unpredictable conditions for log theta (panels A–B) and alpha (panels C–D) power, in anterior (panels A and C) and posterior (panels B and D) ROIs in the 1000 ms following noun onset. Red dashed lines mark windows of significant differences.
Our findings of an effect of noun predictability on frequency power contrast with two previous studies that have found no effects of predictability on frequency power at the critical word onset (Rommers and Federmeier, 2018; Terpønten, 2019). An increase in theta power for unpredictable nouns is consistent with an increase in processing resources being required to retrieve the lexical and semantic information of an unpredictable word, as well as integrate it with the prior sentence context. The experiment presented here was different from previous ones, as we did not find the typical alpha decrease prior to predictable words.

Our findings of an effect of noun predictability on frequency power contrast with two previous studies that have found no effects of predictability on frequency power at the critical word onset (Rommers and Federmeier, 2018; Terpønten, 2019). significantly predicted reduced theta and alpha power at the subsequent noun onset, independently of condition. Prediction of the referent therefore seems to reduce the amount of processing effort required when processing the noun, as is reflected in weaker alpha/theta increases. A relationship between the constraints provided by the verb in a sentence and the ease of subsequent noun processing has previously been found by Maess et al. (2016), who observed a negative correlation between the N400 amplitude at the onset of a constraining verb and the N400 amplitude at the predictable noun. Here the N400 could not be predicted by anticipatory fixations, in line with the absence of an effect of predictability on N400 amplitude. N400 amplitude was, however, related to frequency power at verb onset, dependent on condition. As anterior theta and alpha power in response to the verb increased, N400 amplitude decreased in the predictable congruent condition but increased with anterior theta power in the predictable incongruent condition. These findings corroborate that processing of the preceding contextual constraints facilitated subsequent noun processing when the noun was congruent with the prediction, but may have interfered with processing when the noun was incongruent with the prediction. A relationship between pre-word alpha power and N400 amplitude has previously been found by Lago et al. (2023), where lower pre-word alpha power was associated with larger N400 amplitude in response to incongruent words. These recent findings are difficult to compare with the findings we present here, as we did not find the typical alpha decrease prior to predictable words.
this tentative conclusion is correct, this would confirm the added value of testing hypotheses in environments that are as rich as the settings in which listeners typically process speech in their everyday lives.

Contrary to our hypothesis and the previous literature, we did not observe an effect of noun predictability on the N400 amplitude. Although from Fig. 4 it appears as though the N400 was on average slightly larger in the unpredictable compared to predictable condition, this difference was not significant. These findings contrast with the effect of noun predictability on the pattern of anticipatory fixations in the current study, which show that participants could predict the noun in the predictable but not the unpredictable condition. Thus, together our findings provide concrete evidence supporting that the N400 reflects the amount of new semantic information to be processed upon hearing a noun. This is different from the opposite direction to our expectations and the previous literature (DeLong et al., 2014; Federmeier et al., 2007; Quante et al., 2018; Thornhill and Van Petten, 2012; Van Petten and Luka, 2012). However, our results could be explained in reference to the work by Brothers et al. (2020), where plausible but unexpected words elicited a larger late anterior positivity compared to expected words only when the preceding context was globally rather than locally constraining. Similar to Experiment 2a in Brothers et al. (2020), here the overall sentence context was unconstraining and sentences were only constrained by the verb. Moreover, the verb was always positioned locally to the noun, often only separated with a single preposition and a determiner. The authors propose that post-N400 positivities are elicited only when a substantial situation model has been formed, when the prior linguistic context is rich and constraining. With locally predictive constraints, the predicted event had not yet been built into the situation model, resulting in no requirement for the situation model to be updated. Our findings are also in line with Lau et al. (2013), who found a late negativity, rather than a positivity, in response to unpredictable targets in prime-target word pairs. Again, with word pairs there was no opportunity to build up a rich and meaningful situation model. In relation to the current paradigm, this explanation raises the question of how much time is needed for the listener’s situation model to be updated with the highly constraining information. Our findings also raise the question of to what extent the visual context affects post-N400 effects. If they are indeed reflecting the updating of the situation model then it might be expected for them to also be influenced by visual context constraints. Indeed, situation models should integrate information that is concurrently and consecutively perceived via the different (visual, auditory) modalities and senses.

Alternatively, it may be that the post-N400 effects are task-specific. Previous studies investigating the effect of prediction on post-N400
components have been conducted in the laboratory with (un)constraining sentence stimuli (Brothers et al., 2020; DeLong et al., 2014; Federmann et al., 2007; Kuperberg et al., 2020; Quante et al., 2018; Rommers and Federmann, 2018; Thorhill and Van Petten, 2012; Van Petten and Luka, 2012). Nieuwland et al. (2020) highlighted that components observed over hundreds of milliseconds, like the post-N400, are likely a result of the combined activity of multiple sources, as is evident from source localisation of the magnetoencephalography signal in response to single words (Araña et al., 2020; Huizeling et al., 2021; Pyllkänen and Marantz, 2003). The combination of components contributing to the signal can therefore be expected to be different when the linguistic stimuli are integrated with a rich visual context, as was the case in the present study. In addition to post-N400 effects being task-specific, later components, which are further from the baseline, are more vulnerable to error when traditional baseline correction techniques are used instead of including the baseline as a regressor in the statistical model, as we did here. Indeed, there is evidence to suggest that some post-N400 effects in the literature may be artefactual and disappear when improved baseline correction techniques are applied (Alday, 2019).

4.2. Noun congruence

Consistent with our hypothesis and the previous literature, in the predictable condition the N400 amplitude was significantly smaller when the referent was congruent with the context provided by the visual scene, confirming the listener’s prediction, compared to when the referent was incongruent with the visual context, disconfirming their prediction. These findings are consistent with the wider N400 literature and with multimodal N400 effects to incongruent visual and linguistic information (Stitikova et al., 2008; Willems et al., 2008a,b). A larger N400 amplitude for incongruent nouns likely reflects an increased amount of semantic information to be retrieved and integrated with the prior context at the time of word onset (Brothers and Kuperberg, 2021; Hagoort et al., 2009; Hodapp and Babovsky, 2021; Kutas and Federmann, 2011), in comparison to the congruent condition where the referent was visible and thus some of the semantic features may have already been retrieved prior to word onset.

Effects of noun congruence were found on both theta and alpha power in response to the noun onset, an effect that interacted with ROI for theta frequency. Consistent with the previous literature, higher theta was found in response to incongruent relative to congruent nouns and in the anterior relative to posterior ROI (Bastiaansen and Hagoort, 2015; Li et al., 2017; Rommers et al., 2017; Willems et al., 2008a), an effect that was sustained throughout the 1000ms analysis window after noun onset. An increase in theta power has been observed for both unexpected yet plausible nouns and to semantically anomalous nouns. Higher theta could reflect the retrieval of semantic and lexical information from memory or increased cognitive control to suppress the predicted word and to update the sentence interpretation (Cavanagh and Cohen, 2022; Cavanagh and Frank, 2014; Demiralp and Başar, 1992; Klimesch et al., 1994). It is likely that both information retrieval and cognitive control contributed to increased theta here.

Alpha power was higher in the incongruent relative to congruent condition and was stable across time. The direction of this effect is inconsistent with our hypotheses, where we expected increased attention and processing, and therefore reduced alpha, in the incongruent compared to congruent condition (Rommers et al., 2017; Wang et al., 2012; Willems et al., 2008a). For example, Willems et al. (2008a) found lower alpha power when the linguistic and visual information mismatched the sentence context. In the current paradigm, both the auditorily presented noun and the visual input mismatched the participant’s expectation but were plausible within the sentence context, rather than anomalous. High alpha is often seen during sustained attention and when inhibiting irrelevant distracting information (Dockree et al., 2007; Rihs et al., 2007, 2009). It could be that a stronger inhibitory response is needed to suppress the predicted item in the current paradigm due to the object’s presence in the virtual environment with the participant. Furthermore, increased alpha may reflect the effects of sustained attention, where attention towards the virtual speaker is sustained for longer when the linguistic information is more challenging to process. This could particularly be the case in the rich visual environment in VR where there is additional irrelevant information to inhibit, including the ongoing presence of the predicted object. Indeed, alpha synchronisation has been shown to be associated with suppressing irrelevant information in listening tasks (Dimitrijević et al., 2019; Strauß et al., 2014b). Such speculative hypotheses require further investigation in relation to the current paradigm.

Consistent with our hypotheses and the previous literature, the model estimated the post-N400 response to be more positive in response to incongruent relative to congruent nouns, particularly in the posterior ROI. Typically, a greater anterior positivity has been associated with lexical items that are plausible but unexpected in highly constraining contexts (Brothers et al., 2020; DeLong et al., 2014; Federmann et al., 2007; Kuperberg et al., 2020; Quante et al., 2018; Thorhill and Van Petten, 2012; Van Petten and Luka, 2012), but here the model estimated the positivity to be greater in incongruent relative to congruent nouns in the posterior ROI. The posterior positivity is typically seen in response to anomalous sentence endings and has been argued to reflect an inability to integrate the word with the prior context and a reanalysis of the sentence (Brothers et al., 2020; Kuperberg et al., 2020; Rommers and Federmann, 2018; Van Petten and Luka, 2012). Here we saw a discrepancy between the data plotted in Fig. 5 and the outcome of the model, making our findings difficult to interpret in relation to previous results. Moreover, the differences between the current paradigm and previous reports make it difficult to directly compare our results with the results of others. For example, later effects are further from the baseline and thus more subject to slow drifts in the data. This could be exacerbated in a VR environment, where the participant is making small movements with their head and the data is more vulnerable to environmental noise. Further research is needed to test whether the current post-N400 findings are robust.

4.3. Verb’s predictiveness

Both theta and alpha power were higher in response to predictive relative to unpredictive verbs and changed over time in response to the predictive verbs in an anterior ROI. Theta additionally changed over time in an anterior ROI in response to unpredictive verbs. Higher alpha and theta power in response to predictive relative to unpredictive verbs contrasts with the previous literature. Li et al. (2017) found lower alpha in response to predictive compared to unpredictive verbs and no effect of verb predictivity on theta power. Moreover, numerous studies have found lower alpha power in response to predictive context directly preceding predictable words (Gastaldon et al., 2020; Leon-Cabrera et al., 2022; Li et al., 2017; Molinaro et al., 2017; Piai et al., 2014; Rommers et al., 2017; Roos and Piai, 2020; Terponten et al., 2019; Wang et al., 2018). On inspection of Fig. 8, it appears as though the observed effects are a result of an anterior power increase in a broader theta-alpha frequency band in the predictable condition, ranging from 4 to 12 Hz. This could reflect the same process across frequencies. However, similar broad effects have been found in response to spoken auditory stimuli in past reports and were found to be dissociated across alpha and theta frequency bands at the source level (Strauß et al., 2014a). Conducting source level analysis went beyond the scope of the current paper and so we cannot make any such conclusions here.

In the current data, theta but not alpha power in a posterior ROI predicted more time spent fixating the object, providing the object had been fixated to begin with. Neither theta nor alpha power, however, predicted the binary outcome of whether or not the object was fixated. One reason for this could be that a prediction can take place without an eye movement towards the object. A lack of eye gaze towards the
