Measurement of the top quark mass in the dilepton channel

We present a measurement of the top quark mass in the dilepton channel based on approximately \(370 \text{ pb}^{-1}\) of data collected by the D0 experiment during Run II of the Fermilab Tevatron collider. We employ two different methods to extract the top quark mass. We show that both methods yield consistent results using ensemble tests of events generated with the D0 Monte Carlo simulation. We combine the results from the two methods to obtain a top quark mass \(m_t = 178.1 \pm 8.2 \text{ GeV}\). The statistical uncertainty is 6.7 GeV and the systematic uncertainty is 4.8 GeV.
The top quark mass is an important parameter in standard model [1] predictions. For example, loops involving top quarks provide the dominant radiative corrections to the value of the W boson mass. Precise measurements of the W boson and top quark masses provide a constraint on the Higgs boson mass [2].

At the Tevatron, top and antitop quarks are predominantly pair-produced. Top quarks decay to a W boson and a b-quark. If the W bosons from the top and the antitop quarks both decay leptonically (to e or μ) the final state consists of two charged leptons, missing transverse momentum (p_T) from the undetected neutrinos, and two jets from the fragmentation of the b quarks. We call this the dilepton channel. It has a relatively small branching fraction (≈5%) but very low backgrounds. The measurement of the top quark mass in the dilepton channel is statistically limited. It provides an independent measurement of the top quark mass that can be compared with measurements in other t̅t̅ decay channels, and a consistency check on the t̅t̅ hypothesis in the dilepton channel.

The D0 detector is a multipurpose collider detector [3]. The central tracker employs silicon microstrips close to the beam and concentric cylinders covered with scintillating fibers in a 2 T axial magnetic field. The liquid-argon/uranium calorimeter is divided into a central section covering pseudorapidity $|\eta| \leq 1.1$ and two endcap calorimeters extending coverage to $|\eta| \leq 4.2$ [4], where $\eta = -\ln[\tan(\theta/2)]$ and $\theta$ is the polar angle with respect to the proton beam direction. The muon spectrometer consists of a layer of tracking detectors and scintillation trigger counters between the calorimeter and 1.8 T toroidal iron magnets, followed by two similar layers outside the toroids.

We present here two measurements that were carried out independently by two groups of analyzers. Both groups chose to optimize their analyses in different ways, but taken advantage of the low background in top-antitop samples selected using tagging of b-quark jets. In the end, we combine the results from both analyses taking into account the correlations between the results.

The event selection is based on the measurement of the cross section for t̅t̅-production in the dilepton channel[5] with a few modifications. The analyses use about 370 pb$^{-1}$ of data from pp collisions at $\sqrt{s} = 1.96$ TeV collected with the D0 detector at the Fermilab Tevatron collider.

We select events with two oppositely charged, isolated leptons (e or μ) with transverse momentum $p_T > 15$ GeV and at least two jets with $p_T > 20$ GeV. Electron candidates are isolated clusters of energy in the electromagnetic section of the calorimeter that agree in their profile with that expected from electromagnetic showers, based on Monte Carlo simulations, and that are matched with a charged particle track reconstructed in the central tracker. Electrons must be either in the central calorimeter (pseudorapidity $|\eta| < 1.1$) or in the forward calorimeter (1.5 < $|\eta| < 2.5$). Muons are reconstructed as tracks in the muon spectrometer with $|\eta| < 2$, matched to a charged particle track in the central tracker. They must be isolated from other activity in the calorimeter and in the tracker. Jets are reconstructed with the improved legacy cone algorithm[6] with cone size $\Delta R = \sqrt{\Delta \eta^2 + \Delta \phi^2} = 0.5$ and are restricted to $|\eta| < 2.5$. All jets were corrected using the standard D0 jet energy scale corrections[7].

We distinguish eμ, ee, and μμ events. For eμ events we require $H_T > 122$ GeV, where $H_T$ is the scalar sum of the larger of the two lepton $p_T$ values and the $p_T$ values of the leading two jets. For ee events we require sphericity $S > 0.15$ and missing transverse momentum $p_T > 35 - 40$ GeV, depending on the dielectron invariant mass $m(ee)$, and we reject events with $80 < m(ee) < 100$ GeV to reduce the background from $Z \rightarrow ee$ decays. Sphericity is defined as 1.5 times the sum of the first two eigenvalues of the normalized momentum tensor calculated using all electrons, muons and jets in the event.

For μμ events we require inconsistency with the $Z \rightarrow μμ$ hypothesis based on the $\chi^2$ of a kinematic fit. In some $Z \rightarrow μμ$ events a muon momentum is significantly mismeasured. These events are not consistent kinematically with $Z$ decays and they are therefore not eliminated by the kinematic fit. The mismeasured muon momentum gives rise to $p_T$ imbalance in the muon direction. We therefore require $p_T > 35$ GeV if the azimuthal angle between the leading muon and the direction of $p_T$, $\Delta \phi(p_T, \mu) < 175^\circ$. We tighten the $p_T$ requirement to 85 GeV if the leading muon and the $p_T$ are approximately collinear in the transverse direction.

For our mass measurements we use the following samples of events. The “b-tag” sample consists of events that have at least one jet that contains a secondary vertex tag with transverse decay length significance $\Delta R > 7$ [8]. This sample has very low backgrounds. The “no-tag” sample consists of events that have no such secondary vertex tags. The 26 events in these two samples consist of 20 eμ events, 5 ee, and 1 μμ event.

The “tight” sample does not use the b-tagging information. It contains all ee and μμ events that are in either the b-tag or the no-tag samples. For eμ events the tight sample requires the more restrictive cuts $H_T > 140$ GeV, $p_T > 25$ GeV and tighter electron identification cuts to reduce backgrounds. To increase the acceptance for dilepton decays, we also analyze a sample of events that requires only one well-identified lepton (e or μ) with $p_T > 15$ GeV and an isolated track with $p_T > 15$ GeV instead of the second identified lepton. The events must also have at least one jet with a secondary vertex tag, and $p_T > 15-35$ GeV, depending on lepton flavor and the invariant mass of the lepton+track system. We call this the “ℓ+track” sample. Events with two well-identified
leptons are vetoed from this sample so that there is no overlap between the \(\ell^+\)-track sample and the other dilepton samples. There are 6 \(\ell^+\)-track events and 3 \(\mu^+\)-track events in this sample. The observed event yields for each of the data samples are listed in Table I.

### Table I: Expected and observed dilepton event yields for \(\bar{t}t\) production with \(m_t = 175\) GeV and the backgrounds from WW and Z production based on Monte Carlo, and from misidentified leptons (mis-id) based on collider data.

Monte Carlo samples are generated for nineteen values of the top quark mass between 120 and 230 GeV. The simulation uses ALPGEN [9] with CTEQ5L parton distribution functions [10] as the event generator, PYTHIA [11] for fragmentation and decay, and GEANT [12] for the detector simulation. No parton-shower matching algorithm was used in the generation of these event samples. We simulate diboson production with ALPGEN and PYTHIA and \(Z/\gamma^* \rightarrow \tau\tau\) processes with PYTHIA. The number of expected events are determined by applying the selection cuts to these Monte Carlo event samples. These samples are corrected for lepton, jet and \(b\)-tagging efficiencies determined from collider data.

The tagging efficiency for \(b\)-jets is measured in a data sample enhanced in heavy flavor jets by requiring at least one jet with a muon in each event. Monte-Carlo based corrections are applied to correct for sample biases. The probability to tag a light-flavor jet is measured from collider data using events with a secondary vertex with negative decay length, meaning that the tracks forming the secondary vertex meet in the hemisphere that is on the opposite side of the primary vertex from the jet.

The energy of Monte Carlo jets is increased by 3.4\% in addition to the nominal jet energy scale corrections. This factor was determined by fitting the top mass and the jet energy scale in lepton+jets events and brings the invariant mass distribution of the two jets from the W boson decay in lepton+jets Monte Carlo events in agreement with that observed in the data.

Event yield normalizations for \(Z \rightarrow \ell\ell\) and \(Z \rightarrow \mu\mu\) are obtained from data. The number of events with misidentified leptons is dominated by jets misidentified as electrons. We construct a likelihood discriminant to distinguish electrons from misidentified jets based on the shape of the energy cluster in the calorimeter and the on the matched track. We determine the contamination by misidentified jets in our sample by fitting the distribution of this likelihood discriminant before we cut on it. Expected yields for signal and background are given in Table I.

We use only the two jets with the highest \(p_T\) in this analysis. We assign these two jets to the \(b\) and \(\bar{b}\) quarks from the decay of the \(t\) and \(\bar{t}\) quarks. If we assume a value \(m_t\) for the top quark mass, we can determine the pairs of \(t\) and \(\bar{t}\) momenta that are consistent with the observed lepton and jet momenta and \(p_T\). A solution refers to a pair of top-antitop quark momenta that is consistent with the observed event. For each assignment of observed momenta to the final state particles and for each hypothesized value of \(m_t\), there may be up to four solutions. We assign a weight function \(w(m_t)\) to each solution, as described below. Events for which no solution exists are rejected from our data and Monte Carlo event samples. The event yields in Table I include this additional selection requirement. Two events from the collider data are rejected with this requirement.

We consider each of the two possible assignments of the two jets to the \(b\) and \(\bar{b}\) quarks. We account for detector resolutions by repeating the weight calculation with input values for the lepton and jet momenta that are drawn from the detector resolution functions for objects with the observed momenta. We refer to this procedure as resolution sampling. For each event we obtain a weight \(W(m_t) = 1/N \times \sum_j w(m_t)_{j}\) by summing over all \(n\) solutions and averaging over \(N\) resolution samples. This weight characterizes the likelihood that the event is produced in the decay of a \(\bar{t}t\) pair as a function of \(m_t\).

The techniques we use are similar to those used by the DØ Collaboration to measure the top quark mass in the dilepton channel using Run I data [13]. The data are analyzed using two different methods that differ in the event samples that they are based on, in the calculation of the event weight, and in the algorithm that compares the weights for the observed events to Monte Carlo predictions to extract the top quark mass.

The matrix-element weighting technique (MWT) follows the ideas proposed by Dalitz and Goldstein [14] and Kondo [15]. The solution weight is

\[
w(m_t) = f(x)f(\bar{x})p(E^*_t|m_t)p(E^*_\bar{t}|m_t),
\]

where \(f(x)\) is the parton distribution function of the proton and \(x = 1\) is the momentum fraction carried by the initial (anti)quark. The quantity \(p(E^*_t|m_t)\) is the probability that the lepton has energy \(E^*_t\) in the top quark rest frame for the hypothesized top quark mass \(m_t\).

For each event we use the value of the hypothesized top quark mass \(m_{peak}\) at which \(W(m_t)\) reaches its maximum as the estimator for the mass of the top quark. We generate probability density functions of \(m_{peak}\) for a range of top quark masses using Monte Carlo simulations. We call these distributions templates. To compute the contribution of backgrounds to the templates, we use \(Z \rightarrow \ell\ell\) and WW Monte Carlo events. Backgrounds arising from detector signals that are misidentified as electrons or muons are estimated from collider data samples.

We compare the distribution of \(m_{peak}\) for the observed events to these templates using a binned maximum like-
The likelihood is calculated as
\[ L(m_t) = \prod_{i=1}^{n_{\text{bin}}} \left[ \frac{n_s s_i(m_t) + n_b b_i}{n_s + n_b} \right]^{n_s} \]

where \( n_i \) is the number of data events observed in bin \( i \), \( s_i(m_t) \) is the normalized signal template contents for bin \( i \) at top quark mass \( m_t \), \( b_i \) is the normalized background template contents for bin \( i \). The product runs over all \( n_{\text{bin}} \) bins. The background template consists of events from all background sources added in the expected relative proportions. The signal-to-background fraction is fixed to \( n_s/n_b \) with the numbers of signal and background events \( (n_s, n_b) \) taken from Table I.

To calibrate the performance of our method, we generate a large number of simulated experiments for several input top quark mass values. We refer to each of these experiments as an ensemble. Each ensemble consists of as many events of each type as we have in our collider data sample. A given event is taken from the signal and background samples with probabilities that correspond to the fraction of events expected from each sample. We use a quadratic function of \( m_t \) to fit the \( -\ln L \) points to thirteen mass points centered on the point with the smallest value of \( -\ln L \). The distribution of measured top quark mass values from the ensemble fits gives an estimate of the parent distribution of our measurement. The ensemble test results indicate that the measured mass tracks the input mass with an offset of \( 1.9 \pm 0.8 \) GeV, which we correct for in the final result.

In general, the tails of the likelihood distribution for an ensemble are not well approximated by a Gaussian. Thus it is necessary to restrict the range of mass points that is included in the fit to points near the observed minimum in \( -\ln L \). For small data samples, however, there is a substantial statistical uncertainty in the computed likelihood values which can be reduced by increasing the number of mass points used in the fit. Thus the range of mass points that are included in the likelihood fit must be optimized for the observed data sample size to obtain the best possible agreement between measured top quark mass and input top quark mass. This was done for both analyses based on Monte Carlo ensembles that contain exactly as many events as we observe in the data.

The \( \mathcal{M} \text{WT} \) analysis uses the no-tag and \( b \)-tag samples of events. Separating out the very-low-background \( b \)-tagged events improves the precision of the result. The analysis is performed with separate templates for \( ee, e\mu, \) and \( \mu\mu \) events and separate signal-to-background fractions for events without a \( b \)-tag and \( \geq 1 \) \( b \)-tags. The maximum of the joint likelihood for all events, shown in Fig. 1, corresponds to \( m_t = 176.2 \pm 9.2 \) (stat) GeV after the offset correction. Figure 2 shows the distribution of \( m_{\text{peak}} \) from collider data compared to the sum of Monte Carlo templates with \( m_t = 180 \) GeV.

The neutrino weighting technique (\( \nu \text{WT} \)) ignores the measured \( p_T \) in reconstructing the event. Instead we assume a representative range of values for the pseudora-
The finite size of the Monte Carlo samples limits the statistical precision with which we can extract the top quark mass. This is accounted for in the Monte Carlo statistics uncertainty. Finally, we generated ensembles with varied jet and muon momentum resolutions to estimate the effect of their uncertainties. The resulting uncertainties for the vWT analysis are quoted in Table II. The effect on the result of the MWT analysis was negligible.

We follow the method for combining correlated measurements from Ref. [16] in combining the results from the MWT and vWT analyses. We determine the statistical correlation between the two measurements using ensemble tests. The correlation factor between the two analyses is 0.35. The systematic uncertainties from each source in Table II are taken to be completely correlated between the two analyses. The results of the combination are also listed in Table II.

In conclusion, we measure the top quark mass in the dijet channel. We obtain \( m_t = 178.1 \pm 6.7 \text{(stat)} \pm 4.8 \text{(syst)} \) GeV as our best estimate of the top quark mass. This is in good agreement with the world average \( m_t = 172.5 \pm 2.3 \) GeV [17], based on Run I and Run II data collected by the CDF and DO Collaborations.
