Summary

Juvenile gilthead sea bream were exposed to diluted seawater (2.5% salinity; DSW) for 3 h or, in a second experiment, acclimated to DSW and fed a control or calcium-deficient diet for 30 days. Branchial Ca²⁺ influx, drinking rate and plasma calcium levels were assessed. Sea bream plasma parathyroid hormone related protein (sPTHrP) was measured, and mRNAs of *pthrp*, its main receptor, *pthlr*, and the calcium-sensing receptor (*casr*) were quantified in osmoregulatory tissues and the pituitary gland. When calcium is limited in water or diet, sea bream maintain calcium balance; however, both plasma Ca²⁺ and plasma sPTHrP concentrations were lower when calcium was restricted in both water and diet. Positive correlations between plasma sPTHrP and plasma Ca²⁺ ($R^2=0.30$, $N=39$, $P<0.05$), and plasma sPTHrP and body mass of the fish ($R^2=0.37$, $N=148$, $P<0.001$) were found. Immunoreactive sPTHrP was demonstrated in pituitary gland pars intermedia cells that border the pars nervosa and co-localises with somatolactin. In the pituitary gland, *pthrp*, *pthlr* and *casr* mRNAs were downregulated after both short- and long-term exposure to DSW. A correlation between pituitary gland *pthrp* mRNA expression and plasma Ca²⁺ ($R^2=0.71$, $N=7$, $P<0.01$) was observed. In gill tissue, *pthrp* and *pthlr* mRNAs were significantly upregulated after 30 days exposure to DSW, whereas no effect was found for *casr* mRNA expression.

We conclude that in water of low salinity, declining pituitary gland *pthrp* mRNA expression accompanied by constant plasma sPTHrP levels points to a reduced sPTHrP turnover and that sPTHrP, through paracrine interaction, is involved in the regulation of branchial calcium handling, independently of endocrine pituitary gland sPTHrP.

Key words: PTHrP, calcium balance, pituitary gland, hypocalcemia, *Sparus auratus*.

Introduction

Parathyroid hormone related protein (PTHrP) is a hypercalcemic factor in fish (Guerreiro et al., 2001). Phylogenetically it is the ancestor of parathyroid hormone (PTH), which is the major hypercalcemic hormone in terrestrial vertebrates. A sea bream (*Sparus auratus* L.) *pthrp* cDNA has been cloned (Flanagan et al., 2000) and the genomic structure of *pthrp* was clarified in fugu (*Fugu rubripes* Temminck and Schlegel, 1850) [Power et al., 2000]. Recently, *pth* genes were discovered in the zebrafish (*Danio rerio* Hamilton 1822) genome (Genuse et al., 2004). The two hormones share a high N-terminal amino acid sequence homology and both peptides bind and activate shared G-coupled PTH/PTHrP receptors (Gardella and Jüppner, 2001). Three different PTHrP receptors were identified in fish (PTH1R, PTH2R and PTH3R), of which PTH1R is the most common and shares homology with the mammalian PTH1R (Rubin and Jüppner, 1999).

PTHrP has a key function in several physiological and biochemical processes in fish, including tissue differentiation and proliferation, vitellogenesis (Guerreiro et al., 2002; Bevelander et al., 2006), cortisol production (Rotllant et al., 2005a), calcium regulation (Guerreiro et al., 2001; Abbink et al., 2004) and calcium resorption from bone and scales (Rotllant et al., 2005b), which strongly indicates that PTHrP is involved in (skeletal) calcium physiology. The presence of PTHrP in a large number of tissues suggests PTHrP to be an auto-/intra- or paracrine factor. However, the immunohistochemical detection of PTHrP in the pituitary gland could also suggest a classical endocrine function for PTHrP in fish, as suggested by Danks et al. (Danks et al., 1993).

Fish have access to infinite sources of readily available calcium in the water. Calcium from water and diet can be taken up via gills and intestine, and calcium balance is achieved by branchial efflux and intestinal excretion. About 99% of the total
Calcium in fish is incorporated in the skeleton and dermal scales (Flik et al., 1986); the latter have a protective function, but also serve as an internal calcium buffer. In fish blood, the plasma total calcium concentration is about 2–3 mmol l⁻¹, of which the ionic fraction accounts for about half (Hansen et al., 1991). This ionic fraction is important for numerous physiological and biochemical processes and is therefore tightly regulated within narrow limits by calcemic endocrines (Flik et al., 1995). As the biochemical processes and is therefore tightly regulated within pituitary glands for sPTHrP immunoreactivity.

This study focused on the regulation of the hypercalcemic sPTHrP and the calcium balance in response to a short and long-term calcium constraint in water and/or diet. Juvenile sea bream were rapidly transferred from full-strength seawater (SW; 34‰ salinity; 10.5 mmol l⁻¹ Ca²⁺) to diluted seawater (DSW; 2.5‰ salinity; 0.7 mmol l⁻¹ Ca²⁺) and sampled 3 h later (the short-term experiment). In a second experiment, juvenile sea bream were exposed to SW or DSW and were fed a calcium-sufficient (Ca+) or calcium-deficient (Ca–) diet for 30 days (the long-term experiment). The experiments were carried out under controlled laboratory conditions. Gill Ca²⁺ influx (FinCa²⁺), drinking rate (DR), plasma sPTHrP, as well as plasma total and ionic calcium concentrations were assessed. pithrp, pithlr and casr mRNA expression levels were quantified in gill, intestine, kidney and the pituitary gland and immunostaining was used to examine pituitary glands for sPTHrP immunoreactivity.

**Materials and methods**

**Fish**

Juvenile gilthead sea bream (*Sparus auratus* L.) were obtained from a commercial fish farm (Viveiro Vilanova, Lda., V.N. Milfontes, Portugal) and flown to the Netherlands without mortality. The fish were kept in round 600 l tanks with aerated flow, through a salinity of 34‰ and a temperature of 23±1°C. The fish were fed commercial pellets (Trouvit, Trouw, Putten, The Netherlands) at a ration of 2% of the total body mass daily.

**Experimental set-up**

**Short-term experiment**

Fourteen fish were placed in a tank with identical water conditions as in the stock. After 1 week of acclimatisation, the fish were rapidly transferred to a second tank with identical conditions (SW; control transfer; *N*=7) or to a tank containing diluted seawater of 2.5‰ salinity (DSW; *N*=7). After 3 h, the fish were killed with 2-phenoxyethanol (1:200; Sigma-Aldrich, St Louis, MO, USA) and blood was taken from the caudal vessels using a 1 ml tuberculin syringe, rinsed with 5X diluted sodium heparin (Leo Pharma, Weesp, The Netherlands; 1000 units ml⁻¹). The collected blood was centrifuged at 13 600 g for 10 min and the plasma so obtained stored at −20°C. Fish were not fed for 24 h before sampling.

**Long-term experiment**

Fish (*N*=160) were randomly selected from stock, placed in four round tanks with 40 fish per tank and left to acclimatisse. After 1 week, the salinity was gradually lowered by continuous flow-through with demineralised water until the test salinity of 2.5‰ (0.7 mmol l⁻¹ Ca²⁺) was reached, after 48 h. The diet was changed from control pellets to the test pellets (Hope Farms, Woerden, The Netherlands). The experimental animals were fed first and the controls received an equivalent amount of food as taken up by the experimental fish. After 3 days, the fish fully accepted the new diet and ate all the food provided (2% of the total body mass per day). The four groups of fish included a control (group a: 34‰ salinity; Ca+ diet) and three test groups: group b (34‰ salinity; Ca– diet), group c (2.5‰ salinity; Ca+ diet) and group d (2.5‰ salinity; Ca– diet). After 30 days, the fish were sampled as described for the short-term experiment; on the day before sampling, feeding was discontinued.

**Calcium influx and drinking**

After 30 days into the experiment, 20 fish from each group were randomly selected and placed in two identical vessels. After 24 h of acclimatisation, 55Cr-EDTA (1.9 kBq ml⁻¹) or 45CaCl₂ (2.5 kBq ml⁻¹) was added to the tanks to assess drinking rate (DR) and gill Ca²⁺ influx (FinCa²⁺), respectively (Flik et al., 1985). Fish were sampled 2 h (DR) or 4 h (FinCa²⁺) after addition of the isotopes. Water samples were collected and the fish were killed by adding 2-phenoxethanol (1:200; Sigma-Aldrich) to the water. The fish were rinsed with demineralised water, quick-frozen in solid CO₂ and the frozen intestinal track was removed. Samples were weighed and rapidly digested in H₂O₂ (35%; 2 ml g⁻¹; Lamers & Pleuger, ‘s Hertogenbosch, The Netherlands). Water calcium content was measured with a calcium kit (Roche, Mannheim, Germany; cat. no. 1489216) and radioactivity in the water and digested fish samples was counted with a liquid scintillation counter (Wallac 1410; Wallac, Turku, Finland). An OptiPhase HiSafe 3 liquid scintillation cocktail (Perkin-Elmer, Boston, MA, USA) was added before counting.

DR was calculated as: \( DR = A_t/A_{wtm} \), where \( A_t \) is the total activity of 55Cr-EDTA in the intestinal track (c.p.m.), \( A_{wtm} \) is the total activity in the water (c.p.m. l⁻¹), \( t \) is the exposure time to 55Cr-EDTA (h) and \( m \) is the mass (mg) of the fish (Flik et al., 2002).

FinCa²⁺ was calculated as: \( F_{in}^{Ca^{2+}} = (A_t/C_w)(A_{wtm}) \), where \( A_t \) is the total activity of 45Ca²⁺ in the fish (d.p.m.), \( C_w \) is the calcium concentration in the water (pmol l⁻¹), \( A_{wtm} \) is the total activity in the water (d.p.m. l⁻¹), and \( t \) is the duration of exposure to 45Ca²⁺ (h). There were no differences in total mass between groups, therefore the results are expressed as \( \text{nl h}^{-1} \) (DR) and \( \text{nmol h}^{-1} \) (FinCa²⁺) and were not normalised for body mass (Guerreiro et al., 2004).

**Plasma analyses**

Plasma Ca²⁺ (mmol l⁻¹) was measured using a Stat Profile pHox plus analyser (Nova Biomedical, Waltham, MA, USA). Plasma total calcium (mmol l⁻¹) was assessed using a calcium kit (Roche, Mannheim, Germany) and plasma PTHrP (nmol l⁻¹) was measured with a homologous radioimmunoassay according to the method of Rottlant et al. (Rottlant et al., 2003).
Immunohistochemistry

Juvenile sea bream pituitary glands were fixed in Bouin’s fixative for 90 min, dehydrated and embedded in paraffin wax. Sections were cut at 5 μm and dewaxed using xylene and degraded alcohols. The immunostaining procedure followed the protocols described earlier for PTHrP (Danks et al., 1993) and somatolactin (SL) (Kaneko et al., 1993). Rabbit anti-sea bream (1-34)sPTHrP (1:100) and rabbit anti-rainbow trout SL (1:3000; a generous gift from Dr Sho Kakizawa, Ocean Research Institute, Tokyo, Japan) were used as primary antibodies. For sPTHrP immunostaining, the sensitive immunoperoxidase method with the Vectastain avidin–biotinylated enzyme complex (Vectastain ABC; Vector Laboratories Inc., Burlingame, CA, USA) was used to increase the staining intensity. Periodic-acid Schiff (PAS) staining was used to distinguish the two cell populations that are found in the pituitary gland, the PAS-positive somatolactin cells in the pars intermedia (pi), and the PAS-negative melanocyte stimulating hormone (MSH) cells.

Expression of pthrp, pth1r and casr mRNA

Tissue samples from the gill, kidney, anterior part of the intestine and pituitary gland were collected. Real-time, quantitative PCR (qPCR) was used to quantify the mRNA expression levels for pthrp, pth1r and the casr according to Hang et al. (Hang et al., 2005), with the housekeeping gene β-actin as endogenous control.

Statistics

All data are expressed as means ± standard deviation (s.d.); differences among groups were assessed by ANOVA. Significance of differences was assessed by parametric (Student’s t-test) or non-parametric (Mann–Whitney U-test) when appropriate and P<0.05 was taken as fiducial limit.

Results

Gill calcium influx and drinking rate

Fig. 1A shows that branchial FinCa++ declined significantly from 105±47 and 77±17 nmol h⁻¹ in the SW groups a and b to 21.4±3.7 and 18.0±4.8 nmol h⁻¹ in the DSW groups c and d. This same pattern was found for drinking (Fig. 1B), with a significant decrease from 14.8±6.5 and 10.7±4.7 nl h⁻¹ in SW to 5.2±1.93 and 4.5±1.3 nl h⁻¹ in the DSW groups. Modification of calcium in the diet had no effect on gill FinCa++ or DR.

Plasma analyses

Exposure to DSW for 3 h had no effect on the total and ionic plasma calcium level (Fig. 2A). When calcium was limited in water and/or diet for 30 days, the plasma total calcium concentration decreased in all experimental groups, whereas the ionic fraction decreased only when calcium was limited in both water and diet (1.13±0.05 mmol l⁻¹ Ca²⁺ in group a and 0.93±0.07 mmol l⁻¹ Ca²⁺ in group d).

The plasma sPTHrP level was not affected after exposure to DSW for 3 h (Fig. 2B), with 0.28±0.06 nmol l⁻¹ in the controls and 0.26±0.12 nmol l⁻¹ sPTHrP in the DSW fish. In the long-term experiment, the plasma sPTHrP level had slightly, but significantly, decreased when calcium was limited in both water and diet, from 0.13±0.02 nmol l⁻¹ in the controls (group a) to 0.10±0.04 nmol l⁻¹ in group d (Fig. 2B). The fish from the short-term experiment were transferred to another tank 3 h before sampling, which could have induced a stress response and thus increased cortisol levels. The measured cortisol levels, 42.1±10.1 nmol l⁻¹ (N=7) in the SW fish and 38.5±10.8 nmol l⁻¹ (N=7) in the DSW fish, do not represent stress levels in sea bream (Arends et al., 1999). We thus exclude stress-induced elevated cortisol levels as a cause of the difference seen in sPTHrP levels between the short and long-term experiment. These differences may relate to different body masses of the groups in the short and long-term experiment.

Fig. 3 shows the correlation that was found between plasma Ca²⁺ and plasma sPTHrP (Fig. 3A; R²=0.30, N=39, P<0.05) and between plasma sPTHrP and the wet mass of the fish (Fig. 3B; R²=0.37, N=148, P<0.001) for all the control observations made.

Immunohistochemistry

Immunostaining with antisera to sea bream (1-34)sPTHrP and trout (Oncorhynchus mykiss Walbaum, 1792) SL revealed
PTHrP and calcium regulation in Sparus auratus

Fig. 2. (A) Plasma calcium levels (N=7 for the short-term experiment and N=10 for the long-term experiment) show the strict control of the ionic fraction, which only slightly, but significantly decreased after long-term calcium constraint in both water and diet. (B) In accordance, plasma sPTHrP decreased significantly in group d compared to controls. Asterisks indicate significant difference (P<0.05) from control group a. Values are means ± s.d. SW, full strength seawater; DSW, diluted seawater.

Fig. 3. Positive relationships were found between plasma sPTHrP and (A) plasma ionic calcium (linear regression; $R^2=0.30$, N=39, P<0.05) and between plasma sPTHrP and (B) the body mass of the fish (power function; $R^2=0.37$, N=148, P<0.001).

Discussion

This study provides new key findings about the regulatory role of sPTHrP in the calcium balance of juvenile sea bream under calcium constraint. Branchial $F_{\text{in}}$ Ca$^{2+}$ and DR decreased in DSW; plasma Ca$^{2+}$ had slightly, but significantly, decreased after long-term exposure to limited calcium in both water and diet. Apparently, DSW induces mild hypocalcemia that is not counteracted by increased Ca$^{2+}$ uptake from the water or by drinking. Plasma sPTHrP level decreased after long-term limitation of

Fig. 4. Immunoreactive sPTHrP and SL in pituitary gland pi cells (Fig. 4). The sPTHrP immunoreactivity was found in the PAS-positive SL cells and bordered the pars nervosa (pn). Controls with omission of the first antibody and pre-absorption with sPTHrP confirmed the specificity of sPTHrP immunoreactivity (data not shown).

Pthrp, pthl1 and casr mRNA expression

Expression of pthrp, pthl1 and casr mRNA was significantly downregulated in the pituitary gland of fish exposed to DSW for 3 h (Fig. 5). In kidney, intestine and gill, no effect on pthrp, pthl1 or casr mRNA expression was observed (data for kidney and intestine not shown).

Exposure to DSW for 30 days resulted in significant downregulation of pthrp, pthl1 and casr mRNAs in the pituitary gland when compared with the control group (Fig. 6A). In gills, a significant upregulation of pthrp and pthl1 mRNA was found in the DSW fish, whereas expression of casr mRNA remained constant (Fig. 6B). In intestine and kidney, no differences in expression of pthrp, pthl1 and casr mRNA were found (data not shown).

In the short-term experiment, a strong relationship between plasma Ca$^{2+}$ and pituitary gland pthrp mRNA expression was found in the controls ($R^2=0.71$, N=7, P<0.01), whereas in the DSW group, this relationship was absent. No such samples were available for the long-term experiment.
calcium in both water and diet and plasma sPTHrP correlated with plasma Ca\(^{2+}\) and the body mass of the fish. This points to a decreased calcium turnover under calcium constraint.

Immunoreactive sPTHrP co-localised with immunoreactive SL in PAS-positive cells of the pi in the pituitary gland, indicating that pituitary sPTHrP may be the source of the high plasma sPTHrP levels in the fish.

In the pituitary gland, downregulation of pthrp, pth1r and casr mRNA was observed after both 3 h and 3 days of calcium constraint. In gills, mRNA for pthrp and pth1r was upregulated, but only after 3 days, whereas casr mRNA expression was not affected by calcium restraint. Thus we have evidence for a branchial sPTHrP regulatory system, acting independently of endocrine pituitary gland sPTHrP actions. The branchial chloride cell, being a key factor in calcium uptake in fish (Flik et al., 1995), appears to be fitted with a para-/-auto- or intracrine hypercalcemic hormonal control mechanism. The production of sPTHrP by the chloride cell may be adjusted via CaSR activity. In situ hybridisation experiments are required for confirmation.

**Gill F\(_{in}\) Ca\(^{2+}\) and DR**

Seawater is a strongly hypercalcemic environment for fish (~10 mmol l\(^{-1}\) Ca\(^{2+}\)) and therefore, fish are forced to reduce Ca\(^{2+}\) influx or to actively secrete Ca\(^{2+}\) to compensate for excessive Ca\(^{2+}\) influx. To compensate for osmotic water loss, seawater fish constantly drink water, which at the same time represents a high Ca\(^{2+}\) load. The transepithelial potential in fish is always more positive than the equilibrium potential for Ca\(^{2+}\) across the integument and therefore, the electrochemical gradient for Ca\(^{2+}\) (the driving force for passive Ca\(^{2+}\) movement across the gills), is directed outwards (+30 mV), causing a substantial passive Ca\(^{2+}\) efflux over the leaky branchial epithelium (Flik and Verbost, 1993). The uptake of Ca\(^{2+}\) is therefore not by diffusion, but by active transport.

The DSW (0.7 mmol l\(^{-1}\) Ca\(^{2+}\)) causes a decrease in osmotic exchange, which subsequently results in the measured threefold decline in DR (and a consequent decrease in Ca\(^{2+}\) intake through drinking) and a fivefold decline in gill F\(_{in}\) Ca\(^{2+}\). In a hypotonic solution such as DSW, the osmotic water loss reverses to water gain and the influx of Ca\(^{2+}\) occurs almost entirely via the gills (Flik et al., 1986). The 15 times lower ambient Ca\(^{2+}\) concentration combined with a just five fold decline in F\(_{in}\) Ca\(^{2+}\) points to an increase in Ca\(^{2+}\) influx capacity or efficiency. This could be achieved by an increase in chloride cell density in the branchial epithelium (Flik et al., 1986) and an enhanced prolactin secretion. Low salinity is known to increase prolactin secretion from the pituitary gland (Kaneko and Hirano, 1993) in salt water fishes. Prolactin is known to limit ionic losses and water permeability in osmoregulatory tissues in hyposmotic media and to stimulate Ca\(^{25}\) influx through gills and Ca\(^{2+}\)-ATPase activity in gill plasma membranes (Flik et al., 1994), thereby increasing the Ca\(^{2+}\) influx capacity. The hypercalcemic control by sPTHrP which is shown in this study may connect both factors. This is further strengthened by the observation that gene expression for pthrp in mammals is upregulated in response to increased plasma prolactin levels (Thiede, 1989).

**Endocrinology**

An interesting observation is the relationship between the body mass of the fish and the plasma sPTHrP concentration. In sea bream, the plasma sPTHrP level increases with the body mass and plateaus with increasing mass of the fish, which suggests a decreasing need for hypercalcemic control with increasing body mass. Apparently, hypercalcemic control in juvenile stages is critically dependent on sPTHrP. As the
PTHrP and calcium regulation in Sparus auratus

Fig. 6. Expression of *pthrp*, *pth1r* and *casr* mRNAs (*N*=10) is significantly downregulated in pituitary gland (A) in the fish exposed to low calcium in dilute seawater for 30 days, whereas gill tissue (B) shows a significant upregulation of *pthrp* and *pth1r* mRNAs under these conditions. Asterisks indicate significant difference (*P*<0.05) compared with the controls (group a). Values are means ± s.d.

Immunohistochemistry

In the sea bream pituitary gland, sPTHrP staining was detected in cells of the pi that were near the pn, and these sPTHrP-positive cells were identified as SL-producing cells. This was confirmed in earlier studies, when Rand-Weaver et al. (Rand-Weaver et al., 1991) and Kaneko et al. (Kaneko et al. 1993) found SL staining in PAS-positive cells that border the pn, in several teleosts. Our data confirm an earlier claim by Ingleton et al. (Ingleton et al., 1998) who reported that in sea bream, sPTHrP and SL are both located in the PAS-positive cells and that some cells contained both sPTHrP and SL. SL is a hormone from the *prl* gene family and is structurally related to both PRL and growth hormone. Kakizawa et al. (Kakizawa et al., 1993) studied SL plasma levels and *sl* mRNA expression in rainbow trout and suggested a role for SL in calcium balance and an increased hormone turnover rate at low calcium levels. Changes in SL plasma levels and pituitary gland mRNA expression at low ambient calcium appear only after several days (Kakizawa et al., 1993), which makes short-term effects of SL on calcium balance unlikely. However, the activity of SL-producing cells may be affected indirectly, possibly by the action of PTHrP. Our data show sPTHrP immunostaining in sea bream pituitary gland SL-producing cells and activation of *pthrp* mRNA production in the pituitary gland 3 h after transfer from SW to DSW. It could very well be that, in cells co-expressing *pthrp* and *sl*, the *pthrp* upregulation precedes that of *sl* and therefore the activity of SL in the pituitary gland. Interestingly, the pituitary gland sPTHrP-producing cells colocalise with a sub-population of SL-producing cells, the SLα cells as observed in zebrafish (Zhu et al., 2004).

Expression of *pthrp* and *pth1r* mRNA was found in all tissues examined, indicative of an auto-/para- or intracrine function of sPTHrP. However, circulating plasma PTHrP levels in teleosts and elasmobranches, as well as immunostaining (Trivett et al., 1999) and mRNA expression (Hang et al., 2005)
for \( pthrp \) in pituitary glands have been established, pointing to an endocrine function for PTHrP as well.

Downregulation of \( pthrp \) and \( pth1r \) mRNA in the pituitary gland was established after 3 h of calcium constraint and remained reduced after at least 30 days of calcium constraint. Both a rapid activation of pituitary gland \( sPTHrP \) production and a long-term involvement of \( sPTHrP \) in the adaptation to hypocalcemic media seem required to maintain calcium balance at hypocalcic conditions. This suggestion is supported by the correlations that were found between plasma \( Ca^{2+} \) and pituitary gland \( pthrp \) mRNA expression and between plasma \( Ca^{2+} \) and plasma \( sPTHrP \) protein. However, the downregulation of \( pthrp \) and \( pth1r \) mRNA in the pituitary gland was not accompanied by a change in plasma \( sPTHrP \) levels, which had only slightly decreased in the group that was held in DSW and fed a diet for 30 days. The adaptive response to calcium constraint results in a reduced metabolic clearance of \( sPTHrP \) from the plasma (in contrast to the reported action of \( SL \)), with downregulated mRNA expression in the pituitary gland and unaltered plasma \( sPTHrP \) levels. This points to a differential regulation of release of \( sPTHrP \) and \( SL \) in the cells that co-express these proteins, or alternatively a differential regulation of the two putative SL cell populations, recently reported (Zhu et al., 2004).

The five- to eightfold upregulated peripheral \( pthrp \) and \( pth1r \) mRNA levels that were found in gills after 30 days exposure to low calcium may reflect an adaptive response, possibly as a result of a decreased environmental calcium concentration or the reduced \( sPTHrP \) metabolic clearance from the plasma, by an autoregulatory feedback of \( sPTHrP \) on its own secretion. In earlier studies on mammals, Fujimi et al. (Fujimi et al., 1991) suggested that \( PTH(1-34) \) directly inhibits \( PTH \) secretion in parathyroid cells. In contrast, Lewin et al. (Lewin et al., 2003) hypothesized that \( PTH \) has a positive auto-feedback on its own secretion under hypocalcic conditions in rats.

Flanagan et al. (Flanagan et al., 2000) showed \( PTHrP \) staining in the chloride cells of gills in teleosts and identified these cells as the principal location of \( PTHrP \) in gill tissue. The increase in chloride cell density in diluted seawater conditions could explain the increase in \( pthrp \) mRNA that was found in gills. Chloride cells are the site of branchial \( Ca^{2+} \) uptake in gills and they also contain CaSR; however, expression of \( casr \) mRNA was unaffected in gills after calcium restraint. CaSR is regulated and equipped to respond to the blood \( Ca^{2+} \) level. Fluctuations as small as 0.2 mmol l\(^{-1} \) are sensed (Lopez-Ilasaca et al., 1997), which enables the fish to tightly regulate the blood \( Ca^{2+} \) concentration. In the present study, the plasma \( Ca^{2+} \) level was remarkably constant and maintained within a maximal range of 0.2 mmol l\(^{-1} \) difference when compared with the controls and therefore upregulation of \( casr \) mRNA may not be relevant. In the pituitary gland, a significant downregulation of \( casr \) mRNA was observed after both short-and long-term calcium constraint, indicating that the need for calcium controlled processes had decreased or reflecting a need for desensitisation to \( Ca^{2+} \) signals. Flanagan et al. (Flanagan et al., 2002) located immunostaining for CaSR in cells bordering the pn in both the pi and the pars distalis in the sea bream pituitary gland and suggested a possible feedback between nerve axons from hypothalamic nuclei and pituitary factors affected by calcium. This is supported by the localisation of \( sPTHrP \) in cells near the pn in this study, thereby possibly controlling the upregulation of \( pthrp \) gene expression in the gills.

This research was carried out with financial support from the Commission of the European Union, Quality of Life and Management of Living Resources specific RTD programme (Q5RS-2001-02904). The authors also wish to thank Ms Joana Amaral from Viveiro Villanova, Portugal, for production of superb fish.
