Bose-Einstein correlations of pairs of identical charged pions produced in hadronic Z decays are analyzed in terms of various parametrizations. A good description is achieved using a Lévy stable distribution in conjunction with a hadronization model having highly correlated configuration and momentum space, the τ-model. Using these results, the source function is reconstructed.

Keywords: Bose-Einstein Correlations

I. INTRODUCTION

Intensity interferometry provides a direct experimental method to determine the sizes, shapes and lifetimes of particle-emitting sources [1–5]. In particular, boson interferometry provides a tool to investigate the space-time structure of particle production processes, since Bose-Einstein correlations (BEC) of two identical bosons reflect both geometrical and dynamical properties of the particle radiating source.

Here we study BEC in hadronic Z decay. We investigate various static parametrizations of the correlation function in terms of the four-momentum difference, \( Q = \sqrt{-(p_1 - p_2)^2} \) and find that none give an adequate description. However, within the framework of models assuming strongly correlated coordinate and momentum space a good description is achieved. We then reconstruct the complete space-time picture of the particle emitting source.

The data were collected by the L3 detector at an e+e− center-of-mass energy of \( \sqrt{s} \approx 91.2 \) GeV. Approximately 36 million like-sign pairs of well-measured charged tracks from about 0.8 million hadronic Z decays are used [6].

We perform analyses on the complete sample as well as on two- and three-jet samples. The latter are found using calorimeter clusters with the Durham jet algorithm with jet resolution parameter \( \chi_{\text{cut}} = 0.006 \). To determine the thrust axis of the event we also use calorimeter clusters.

II. BOSE-EINSTEIN CORRELATION FUNCTION

The two-particle correlation function of two particles with four-momenta \( p_1 \) and \( p_2 \) is given by the ratio of the two-particle number density, \( \rho_2(p_1, p_2) \), to the product of the two single-particle densities, \( \rho_1(p_1)\rho_1(p_2) \). Since we are interested only in the correlation, \( R_2 \), due to Bose-Einstein interference, the product of single-particle densities is replaced by \( \rho_0(p_1, p_2) \), the two-particle density that would occur in the absence of BEC:

\[
R_2(p_1, p_2) = \frac{\rho_2(p_1, p_2)}{\rho_0(p_1, p_2)}. \tag{1}
\]

This \( \rho_2 \) is corrected for detector acceptance and efficiency using Monte Carlo (MC) events, to which a full detector simulation has been applied, on a bin-by-bin basis. An event mixing technique is used to construct \( \rho_0 \). Since all correlations are removed, not just BEC, \( \rho_0 \) is corrected for this [6, 7] using the JETSET Monte Carlo generator [8].

Since the mass of the identical particles of the pair is fixed, \( R_2 \) is defined in six-dimensional momentum space. Since BEC can be large only at small \( Q \), they are often parametrized in this one-dimensional momentum space. But there is no reason to expect the hadron source to be spherically symmetric in jet fragmentation. Recent investigations have, in fact, found an elongation of the source along the jet axis [7, 9–11]. While this effect is well established, the elongation is actually only about 20%, which suggests that a parametrization in terms of the single variable \( Q \), may be a good approximation.

On the other hand, in heavy-ion and hadron-hadron interactions BEC are found not to depend simply on \( Q \), but on components of the momentum difference separately [5, 12–16]. However, in e+e− annihilation at lower energy [17] it has been observed that \( Q \) is the appropriate variable. We confirm that this is indeed the case: We observe [6], both for 2-jet and 3-jet events, that \( R_2 \) does not decrease when both \( q^2 = (p_1 - p_2)^2 \) and \( q_0^2 = (E_1 - E_2)^2 \) are large while \( Q^2 = q^2 - q_0^2 \) is small, but is maximal for \( Q^2 = q^2 - q_0^2 = 0 \), independent of the individual values of \( q \) and \( q_0 \). The same is observed in a different decomposition: \( Q^2 = Q_{L, B}^2 + Q_{T, B}^2 \), where \( Q_{L, B}^2 = (p_{1L} - p_{2L})^2 \) is the component transverse to the thrust axis and \( Q_{T, B}^2 = (p_{1T} - p_{2T})^2 - (E_1 - E_2)^2 \) combines the longitudinal momentum and energy differences. Again, \( R_2 \) is maximal along the line \( Q = 0 \). Hence, a parametrization in terms of \( Q \) can be considered adequate for the purposes of this article.
III. PARAMETRIZATIONS OF BEC

With a few assumptions [2, 5, 18], \( R_2 \) is related to the Fourier transformed source distribution:

\[
R_2(p_1, p_2) = \gamma \left[ 1 + \lambda \exp \left( - (RQ)^2 \right) \right] \left[ 1 + \delta Q \right],
\]

where \( f(x) \) is the (configuration space) density distribution of the source, and \( \tilde{f}(Q) \) is the Fourier transform (characteristic function) of \( f(x) \). The parameter \( \lambda \) is introduced to account for several factors, such as the possible lack of complete incoherence of particle production and the presence of long-lived resonance decays if the particle emission consists of a small, resolvable core and a halo with experimentally unresolved large length scales [19, 20]. The parameter \( \gamma \) and the \((1 + \delta Q)\) term parametrize possible long-range correlations not adequately accounted for in the reference sample. While there is no guarantee that \((1 + \delta Q)\) is the correct form, we will see that it does provide a good description of \( R_2 \) in the region \( Q > 1.5 \) GeV.

A. Static parametrizations

The simplest assumption is that the source has a symmetric Gaussian distribution, in which case

\[
R_2(Q) = \gamma \left[ 1 + \lambda \exp \left( - (RQ)^2 \right) \right] \left[ 1 + \delta Q \right] .
\]  

(3)

Fits of Eq. (3) to the data result in an unacceptably low confidence level, both for two-jet and for three-jet events. The fits are particularly bad at low \( Q \) values, where the parametrization underestimates the height of the peak. We conclude that the shape of the source deviates from a Gaussian.

A model-independent way to study deviations from Eq. (3) is to use [5, 21, 22] the Edgeworth expansion about a Gaussian. Keeping only the first non-Gaussian term, we have

\[
R_2(Q) = \gamma \left[ 1 + \lambda \exp \left( - (RQ)^2 \right) \right] \left[ 1 + \frac{\kappa}{3!} H_3(RQ) \right] \left[ 1 + \delta Q \right] ,
\]

(4)

where \( \kappa \) is the third-order cumulant moment and \( H_3(RQ) \equiv (\sqrt{2}RQ)^3 - 3\sqrt{2}RQ^3 \) is the third-order Hermite polynomial. The second-order cumulant corresponds to the radius \( R \).

Fits of Eq. (4) to the two-jet and three-jet data are indeed much better than the purely Gaussian fits. However, the confidence levels are still marginal, and close inspection shows that the fit curves are systematically above the data in the region 0.6–1.2 GeV and that the data for \( Q > 1.5 \) GeV appear flatter than the fit. This is also the case for the purely Gaussian fit.

The symmetric Lévy stable distribution has three parameters, \( x_0 \), \( R \), and \( \alpha \). Its characteristic function can be written as

\[
\tilde{f}(Q) = \exp \left( iQx_0 - \frac{|RQ|^\alpha}{2} \right) .
\]

(5)

The index of stability, \( \alpha \), satisfies the inequality \( 0 < \alpha < 2 \). The case \( \alpha = 2 \) corresponds to a Gaussian source distribution with mean \( x_0 \) and standard deviation \( R \). For more details, see, e.g., [23]. \( R_2 \) has the following form [24]:

\[
R_2(Q) = \gamma \left[ 1 + \lambda \exp \left( - (RQ)^\alpha \right) \right] \left[ 1 + \delta Q \right] .
\]

(6)

From the fit of Eq. (6) to the two-jet data, shown in Fig. 1, it is clear that the correlation function is far from Gaussian: \( \alpha = 1.34 \pm 0.04 \). The confidence level, although improved compared to the fit of Eq. (3), is still unacceptably low, in fact worse than that for the Edgeworth parametrization. The same is true for 3-jet events.

Both the symmetric Lévy parametrization and the Edgeworth parametrizations do a fair job of describing the region \( Q < 0.6 \) GeV, but fail at higher \( Q \). \( R_2 \) in the region \( Q > 1.5 \) GeV is nearly constant (\( \approx 1 \)). However, in the region 0.6–1.5 GeV \( R_2 \) has a smaller value, dipping below unity, indicative of an anti-correlation. This is clearly seen in Fig. 1 by comparing the data in this region to an extrapolation of a linear fit, Eq. (6) with \( \lambda = 0 \), in the region \( Q > 1.5 \) GeV. The inability to describe this dip in \( R_2 \) is the primary reason for the failure of both parametrizations.

B. Time dependence of the source

The parametrizations discussed so far all assume a static source. The parameter \( R \), representing the size of the source as seen in the rest frame of the pion pair, is a constant. It has, however, been observed that \( R \) depends on the transverse mass, \( m_t = \sqrt{\vec{p}_t^2 + \vec{p}_t^2} = \sqrt{E^2 - p_t^2} \), of the pions [25, 26]. It has been shown [27, 28] that this dependence can be understood if the produced pions satisfy, approximately, the (generalized) Bjorken-Gottfried condition, whereby the four-momentum of a particle and the space-time position at which it is produced are linearly related: \( \vec{x}^t = d\vec{k}^t \). Such a correlation is also a feature of the Lund string model as incorporated in JETSET, which is very successful in describing detailed features of the hadronic final states of \( e^+ e^- \) annihilation.

In the previous section we have seen that BEC depend, at least approximately, only on \( Q \) and not on its components separately. Further, we have seen that \( R_2 \) in the region 0.6–
1.5 GeV dips below its values at higher $Q$. A model which predicts such $Q$-dependence while incorporating the Bjorken-Gottfried condition is the $\tau$-model.

1. The $\tau$ model

A model of strongly correlated phase-space, known as the $\tau$-model [29], explains the experimentally found invariant relative momentum dependence of BEC in $e^+e^-$ reactions. This model also predicts a specific transverse mass dependence of $R_2$, that we subject to an experimental test here.

In this model, it is assumed that the average production point in the overall center-of-mass system, $\bar{x} = (\bar{T}, \bar{x}_r, \bar{r}_z)$, of particles with a given four-momentum $k$ is given by

$$\bar{x}^\mu(k^\mu) = dk^\mu.$$  
(7)

In the case of two-jet events,

$$d = \tau/m_t,$$  
(8)

where $m_t$ is the transverse mass and $\tau = \sqrt{\tau_x^2 - \tau_r^2}$ is the longitudinal proper time $^1$. For isotropically distributed particle production, the transverse mass is replaced by the mass in Eq. (8), while for the case of three-jet events the relation is more complicated. The second assumption is that the distribution of $x^\mu(k^\mu)$ about its average, $\delta_{\bar{x}}(x^\mu(k^\mu) - \bar{x}^\mu(k^\mu))$, is narrower than the proper-time distribution.

$$S(x,k) = \int_0^\infty d\tau H(\tau) \delta_{\bar{x}}(x - \bar{x}(k)) p_1(k),$$  
(9)

where $H(\tau)$ is the longitudinal proper-time distribution, the factor $\delta_{\bar{x}}(x - \bar{x}(k))$ describes the strength of the correlations between coordinate- and momentum-space variables and $p_1(k)$ is the experimentally measurable single-particle spectrum.

$S(x,k)$ and $p_2(k_1,k_2)$ are related in the plane-wave approximation, by the Yano-Koonin formula [30]:

$$p_2(k_1,k_2) = \int d^4x_1 d^4x_2 S(x_1,k_1) S(x_2,k_2) \left(1 + \cos \left[\frac{1}{2} \left(|k_1 - k_2| |x_1 - x_2|\right)\right]\right).$$  
(10)

Approximating $\delta_{\bar{x}}$ by a Dirac $\delta$-function, the argument of the cosine becomes $(k_1 - k_2)(x_1 - x_2) = -0.5(d_1 + d_2)Q^2$. Then $R_2$ is approximated by

$$R_2(k_1,k_2) = 1 + \lambda R(\frac{Q^2}{2m_t}),$$  
(11)

where $R(\omega) = \int d\tau H(\tau) \exp(i\omega\tau)$. Then Eq. (11) becomes

$$R_2(Q, m_t) = \gamma \left[1 + \lambda \exp \left(\frac{\Delta Q^2}{2m_t}\right)\right] \left(1 + \delta Q\right).$$  
(13)

2. The $\tau$ model for average $m_t$

Before proceeding to fits of Eq. (13), we first consider a simplification obtained by assuming (a) that particle production starts immediately, i.e., $\tau_0 = 0$, and (b) an average $m_t$-dependence, which is implemented in an approximate way by defining an effective radius, $R = \sqrt{\Delta \tau/(2m_t)}$. This results in

$$R_2(Q) = \gamma \left[1 + \lambda \cos \left(\frac{\Delta Q^2}{2m_t}\right) \exp \left(-\frac{\Delta Q^2}{2m_t}\right)\right] \left(1 + \delta Q\right),$$  
(14)

where $R_a$ is related to $R$ by

$$R_a^{2a} = \tan \left(\frac{\Delta \tau}{2}\right) R^{2a}.$$  
(15)

Fits of Eq. (14) are first performed with $R_a$ as a free parameter. The fit results obtained, for two-jet, three-jet, and all events are listed in Table I and shown in Fig. 2 for two-jet events. They have acceptable confidence levels, describing well the dip in the 0.6–1.5 GeV region, as well as the low-$Q$ peak.

The fit parameters for the two-jet events satisfy Eq. (15). However, those for three-jet and all events do not. We note that the values of the parameters $\alpha$ and $R$ do not differ greatly between 2- and 3-jet samples, the most significant difference appearing to be nearly $3\sigma$ for $\alpha$. However, these parameters are rather highly correlated which makes the simple calculation of the statistical significance of differences in the parameters unreliable.

Fit results imposing Eq. (15) result, for two-jet events, in values of the parameters which are the same as in the fit with $R_a$ free—only the uncertainties have changed. For three-jet and all events, the imposition of Eq. (15) results in values of $\alpha$ and $R$ closer to those for two-jet events, but the confidence levels are very bad, a consequence of incompatibility with Eq. (15), an incompatibility that is not surprising given that Eq. (8) is only valid for two-jet events. Therefore, we only consider two-jet events in the rest of this article.

$^1$ The terminology ‘longitudinal’ proper time and ‘transverse’ mass seems customary in the literature even though their definitions are analogous $\tau = \sqrt{\tau_x^2 - \tau_r^2}$ and $m_t = \sqrt{E^2 - \vec{p}_t^2}$. Since there is no particle production before the onset of the collision, $H(\tau)$ should be a one-sided distribution. We choose a one-sided Lévy distribution, which has characteristic function [24] (for $\alpha 
eq 1$—see, e.g., [23] for the special case $\alpha = 1$)

$$\tilde{H}(\omega) = \exp \left[-\frac{1}{2} \left(\Delta \tau|\omega|\right)\left(1 - i \text{sign}(\omega) \tan \left(\frac{\Delta \tau}{2}\right)\right) + i \omega \tau_0\right]$$  
(12)

where $\tau_0$ is the proper time of the onset of particle production and $\Delta \tau$ is a measure of the width of $H(\tau)$. Then Eq. (11) becomes

$$R_2(Q, m_t) = \gamma \left[1 + \lambda \cos \left(\frac{\tau_0 Q^2}{m_t} + \tan \left(\frac{\Delta \tau}{2}\right) \frac{\Delta Q^2}{2m_t}\right)\right] \left(1 + \delta Q\right).$$  
(13)
The curve corresponds to the fit of the one-sided Lévy parametrization, Eq. (14). The dashed line represents the long-range part of the fit, i.e., $\gamma(1 + s \Omega)$.

TABLE I: Results of fits of Eq. (14) for two-jet, three-jet, and all events. The uncertainties are only statistical.

3. The $\tau$ model with $m_t$ dependence

Fits of Eq. (13) to the two-jet data are performed in several $m_t$ intervals. The quality of the fits is acceptable and the fitted values of the parameters, $\alpha$, $\tau_0$, and $\Delta \tau$, are stable and within errors independent of $m_t$, as expected in the $\tau$-model. Their values, $\tau_0 \approx 0$ fm, $\alpha \approx 0.38 \pm 0.05$ and $\Delta \tau \approx 3.5 \pm 0.6$ fm, are consistent with the fit of Eq. (14) in the previous section, including the value of $R$, which, combined with the average value of $m_t$ (0.563 GeV), corresponds to $\Delta \tau = 3.5$ fm.

IV. THE EMISSION FUNCTION OF TWO-JET EVENTS

Using the $\tau$-model, we now reconstruct the space-time picture of the emitting process for two-jet events. The emission function in configuration space, $S(x)$, is the proper time derivative of the integral over $k$ of $S(x, k)$, which is given by Eq. (9). Approximating $\delta_\Delta$ by a Dirac $\delta$-function yields

$$S(x) = \frac{d^3 n}{d^3 r} = \left(\frac{m_t}{\tau}\right)^3 H(\tau)p_1 \left(\frac{k - m_t r}{\tau}\right).$$

To simplify the reconstruction of $S(x)$ we assume that it can be factorized: $S(r, z, t) = I(r)G(\eta)H(\tau)$, where $I(r)$ is the single-particle transverse distribution, $G(\eta)$ the space-time rapidity distribution, and $H(\tau)$ the proper-time distribution. With the $\tau$-model’s strongly correlated phase-space, $\eta = y$ and $r = p_t/\tau_m$. Hence, $G(\eta) = N_y(\eta)$ and $I(r) = \left(\frac{m_t}{\tau}\right)^3 N_p(r_{m_t}/\tau)$, where $N_y$ and $N_p$ are the single-particle inclusive rapidity and $p_t$ distributions, respectively. The factorization of transverse and longitudinal distributions has been checked. The distribution of $p_t$ is, to a good approximation, independent of $y$ [6].

With these assumptions and using $H(\tau)$ as obtained from the fit of Eq. (13) together with the inclusive rapidity and $p_t$ distributions [6], the full emission function is reconstructed. Its integral over the transverse distribution is plotted in Fig. 3. It exhibits a “boomerang” shape with a maximum at low $t$ and $z$ but with tails reaching out to very large values of $t$ and $z$. 

FIG. 3: The temporal-longitudinal part of the source function normalized to the average number of pions per event.

FIG. 4: The transverse source function normalized to the average number of pions per event for various proper times.
a feature also observed in hadron-hadron [31] and heavy ion collisions [32]. The transverse part of the emission function, obtained by integrating over $z$ and azimuthal angle, is shown in Fig. 4 for various proper times. Particle production starts immediately, increases rapidly and decreases slowly, forming an expanding ring-like structure.

V. DISCUSSION

BEC of all events as well as two- and three-jet events are observed to be well-described by a Lévy parametrization incorporating strong correlations between configuration- and momentum-space. A Lévy distribution arises naturally from a fractal, or from a random walk or anomalous diffusion [33], and the parton shower of the leading log approximation of QCD is a fractal [34-36]. In this case, the Lévy index of stability, $\alpha_s$, is related to the strong coupling constant, $\alpha_s$ [37, 38]:

$$3\alpha_s = 2\alpha^2.$$  (17)

Assuming (generalized) local parton hadron duality [39-41], one can expect that the distribution of hadrons retains the features of the gluon distribution. Using the value of $\alpha$ found in fits of Eq. (14) for two-jet events we find $\alpha_s = 0.37 \pm 0.04$. This is a reasonable value for a scale of 1–2 GeV, which is where the production of hadrons takes place. For comparison, from $\tau$ decay, $\alpha_s(m_t \approx 1.8$ GeV) = $0.35 \pm 0.03$ [42].

It is of particular interest to point out the $m_t$ dependence of the “width” of the source. In Eq. (13) the parameter associated with the width is $\Delta t$. Note that it enters Eq. (13) as $\Delta t Q^2/m_t$. In a Gaussian parametrization the radius $R$ enters the parameterization as $R^2 Q^2$. Our observance that $\Delta t$ is independent of $m_t$ thus corresponds to $R \approx 1/\sqrt{m_t}$ and can be interpreted as confirmation of the observance [25, 26] of such a dependence of the Gaussian radii in 2- and 3-dimensional analyses of $Z$ decays. The lack of dependence of the parameters of Eq. (13) on $m_t$ is in accordance with the $\tau$-model.

Using the BEC fit results and the $\tau$-model, the emission function of two-jet events is reconstructed. Particle production begins immediately after collision, increases rapidly and then decreases slowly, occuring predominantly close to the light cone. In the transverse plane a ring-like structure expands outwards, which is similar to the picture in hadron-hadron interactions but unlike that of heavy ion collisions.
