Adolescent development

Advice in ABC of adolescence is potentially misleading

Editor—Christie and Viner say that delayed puberty in boys can be quite distressing but is almost always a normal variant. They say that boys aged 15 or over with a testicular volume of 4 ml or more can be reassured that puberty is beginning and, by inference, do not require referral to a specialist. This advice is potentially misleading. For all that it is a variant of normality, constitutional delay in growth and puberty can have adverse psychosocial and skeletal consequences.1 To deny an apubertal teenager the opportunity to choose low dose androgen treatment until he is into his 16th year would be unusual by present standards. Given the likely ensuing timescale, his doctor might as well refer him straight to an endocrinologist instead of a paediatrician. A testicular volume of 4 ml is well within the range found in boys with irreversible hypogonadotrophic hypogonadism and therefore by no means necessarily indicates that puberty is beginning. Many boys with hypogonadotrophic hypogonadism start puberty but fail to progress beyond the early stages. Moreover, a history of cryptorchidism (especially if bilateral) or anosmia should prompt an even earlier referral. Neither does a family history of pubertal timing with young people. However, newer larger studies have shown that boys who are small or whose adolescence is delayed are not psychologically disadvantaged. Rather than overtreating numbers of normal boys, we focus on improving the communication skills of general practitioners in discussing issues such as pubertal timing with young people.

Author’s reply

Editor—Quinton acknowledges that apparent pubertal delay is a normal variant in most boys seen by general practitioners or by paediatric endocrinologists. However, he says that our advice, that boys aged 15 or over with a testicular volume of 4 ml or more can be reassured that puberty is beginning, is potentially misleading, as 4 ml testes are within the range found in adult men with the uncommon condition of irreversible hypogonadotrophic hypogonadism.

Our advice is appropriate for boys who present to general practitioners. The absence of any signs of puberty, or lack of further progression through puberty over the next six months should, of course, be viewed with suspicion and merit referral to a paediatric endocrinology service for full investigation, including consideration of conditions such as hypogonadotrophic hypogonadism.

Quinton thinks that even the normal variant of constitutional delay in growth and puberty can have adverse psychosocial consequences. However, newer larger studies have shown that boys who are small or whose adolescence is delayed are not psychologically disadvantaged. Rather than focusing on the improvement of the communication skills of general practitioners in discussing issues such as pubertal timing with young people.

Cognitive behaviour therapy for adolescents with chronic fatigue syndrome

Data are insufficient and conclusion inappropriate

Editor—I have concerns about the design and interpretation of the study reported by Stulmeneier et al on cognitive behaviour therapy for adolescents with chronic fatigue syndrome.1 The trial arms were not matched for the number of contacts with healthcare professionals. Experience from larger and more carefully controlled randomised interventional trials of patients with chronic fatigue syndrome has clearly shown that short term improvement in symptoms is related directly to the maintenance of regular contacts with healthcare professionals rather than the therapeutic effect of the intervention itself and consequently, the improvement is not sustained once the contact is lost.

The authors did not offer patients in their waiting list the opportunity to meet therapists regularly for five months but without having cognitive behaviour therapy. Few follow up data on patients in the intervention arm show that the specific treatment benefit was carried forward without regular contacts with the therapists. A cautious approach is essential in inferring direct benefit from cognitive behaviour therapy in the intervention arm (as opposed to short term benefit from close contact with therapists).

The level of activity in some of their participants whom the authors considered to be passive remained unclear.

In their summary points the authors claim that cognitive behaviour therapy was effective by challenging patients’ belief that activity aggravated symptoms. Epidemiological data, however, confirm that fatigue made worse by exercise is a characteristic feature of adolescents at risk of chronic fatigue syndrome. Encouraging activity in disabled patients is entirely different from challenging an accepted feature of the disease. A rhetorical approach towards a physically and emotionally challenging condition does not help recovery and only encourages therapeutic failure.

relatively active patients, based on actometry, distinction between physically passive and results show that this is possible. The activities in a systematic and safe way. Our is possible. Thus, patients are taught to activity related cognitions, activity regulation symptoms. By challenging these and other activity related beliefs, activity regulation, although functional in the first phase of the condition, is dysfunctional in the longer term and maintains activity avoidance and the term and maintains activity avoidance and symptoms. By challenging these and other activity related cognitions, activity regulation is possible. Thus, patients are taught to regulate and increase their physical and other activities in a systematic and safe way. Our results show that this is possible. The distinction between physically passive and relatively active patients, based on actometry, is helpful to select the correct approach to help the patient.

As in other chronic conditions, we do not have one treatment that leads to recovery in all patients. We believe that our study clearly shows that many of the participants benefited from cognitive behaviour therapy and were able to function as normal adolescents again.

How to prevent caesarean deliveries deserves more study

Entror—Declercq et al bring to light “no indicated risk” as a new classification of caesarean delivery. Like other classes of caesarean delivery, annual rates of caesarean sections with no indicated risk have been increasing in the United States and around the world. In the context of these increases, we are surprised that methods of care that might prevent caesarean delivery have not been pursued more aggressively.

Caesarean delivery is strongly correlated to the age of the mother, parity, and increasing gestational age within the term period of pregnancy. If caesarean delivery is an adverse outcome worthy of prevention, if risk factors for caesarean delivery can be identified, and if a latent period exists between the identification of risk and the development of situations requiring caesarean delivery then perhaps a preventive approach—encouraging patients with risk factors to enter labour before their risk can become disease—could lower caesarean delivery rates safely.

Our working group recently described the use of risk driven, prostaglandin assisted induction of labour, and this intervention was associated with a rate of caesarean delivery of only 4%. While Declercq et al think that research should be done to elucidate whether the risks of primary caesarean delivery in cases of no indicated risk will be offset by associated benefits, we hope that an equal amount of time and effort will be spent on developing and testing methods that might safely prevent, or lower, rates of caesarean delivery performed for this and the other more traditional indications.

Early epidurals increase caesarean rate, meta-analysis shows

Entror—The study reported by Mayor in her news item uses the term “neuropsychal analgesia” and claims that early epidurals do not increase the rate of caesarean deliveries. This is confusing as the study was not of early epidural analgesia, and the oxytocin augmentation rate of 75% at first analgesia makes for lack of generalisability.

The claim that women need not worry that early epidurals will lead to increased caesareans is false. This trial was about two methods of helping women with pain in early labour. In the so called epidural arm, on their first request for analgesia, women received intrathecal fentanyl, and in the narcotic arm, hydromorphone. On their second request, almost two thirds of women in both arms were 4 cm or more dilated. In the intrathecal “epidural” arm, they received low dose epidurals in the narcotic arm, hydromorphone.

This trial, as others that have contributed to the Cochrane meta-analysis, showed no increase in caesareans in the presence of epidural analgesia, but does not acknowledge that most women were in active labour at randomisation, which might well do well. Wong et al, like Sharma et al, the major contributors to the Cochrane meta-analysis, have shown only that when women’s pain in the latent phase is managed with intrathecal, narcotic, or other pharmacological or non-pharmacological means, an epidural in the active phase of labour does not increase the rate of caesareans.

The role of an early epidural in contributing to increases in caesarean rates has yet to be studied in an randomised controlled trials, but the sensitivity analysis in the Cochrane meta-analysis, after removing late randomisation studies, shows that early epidurals to more than double caesarean rates.

description of the syndrome includes four primary features: autonomic lability, hyperthermia (pyrexia) without other cause, extrapyramidal syndrome (cog-wheel or lead pipe rigidity), and encéphalopathy. Despite superficial clinical similarities between neuroleptic malignant syndrome and serotonin syndrome, they are usually easily differentiated on the basis of careful neurological examination. Neuroleptic malignant syndrome is associated with lead pipe rigidity, bradykinesia, and other extrapyramidal features. Conversely in serotonin syndrome there is hyperkinesia, hyperreflexia, and clonus.

Descriptions of adverse reactions to psychotropic drugs need detailed clinical descriptions of neuromuscular, central, and autonomic features. Using ambiguous or non-specific criteria to label adverse reactions as a particular syndrome while ignoring the pharmacology of the implicated drug may lead to false associations between particular drugs and clinical syndromes and to inappropriate treatment.

Authors’ reply
Edtror—Clomipramine is not a neuroleptic and cannot be considered as an “antidepressant.” However, as mentioned in our article, this drug has an appreciable blocking effect at dopamine receptor sites, the traditional domain of the neuroleptic drug. This is a weak effect, but it is more potent than several other antidepressant agents. This effect is recognised in the current edition of the BNF, which says that neuroleptic malignant syndrome may, very rarely, arise in the course of antidepressant treatment.

Reference to 50 worldwide reports received regarding clomipramine and neuroleptic malignant syndrome or suspected neuroleptic malignant syndrome, in addition to four reports received by the Committee on Safety of Medicines and two published case reports. We agree that we should have made clear that this patient’s muscle rigidity was of the lead pipe variety, although some widely accepted diagnostic criteria require only severe muscle rigidity. The diagnostic criteria that we tabulated were based on Levinson and Sternbach and referenced in our article.1

We described in this patient an earlier diagnosed episode of serotonin syndrome, and no clinical evidence of rigidity was found on that occasion.

In view of the action at dopamine sites of clomipramine, and the statement in the BNF from the BMA and the Royal Pharmaceutical Society of Great Britain, we would continue to support our diagnosis of neuroleptic malignant syndrome in this informative case.

Risks of gene therapy should be weighed against lack of alternatives for many diseases

Artwork of gene therapy

Editor—Kimmelman provided a comprehensive discussion about the risks and ethics of gene therapy. We certainly cannot predict the future, but the risks should be weighed against the complete lack of alternative options for many diseases discussed.

The two cases of T cell leukaemia in the X-linked severe combined immunodeficiency gene therapy trial are presented as typical examples of malignant transformation. However, that treatment entailed the modification of immature stem cells, which may present additional risks. Much work is being done in vector design to lessen these risks. Relative risks and toxicities are also likely to be linked to the disease type and target cell. For non-renal disorders such as the inherited retinal dystrophies, minimising risk is of even more importance. However, gene transfer to a post-mitotic cell such as a photoreceptor by using a vector with limited genomic integra-
both arms in proportions reflective of the population that will perform the operations. Academics can analyse the “expertise” subgroups, while the rest of us can look at the overall results to determine how an operation will really perform. Surgical research shares many similarities with psychotherapy research Editor—Of course the expertise based randomised trial, mooted for surgical procedures by Devereaux et al., is the norm in psychotherapy research when comparing two different psychotherapies. A similar debate on the interpretation of such trials occurred in the psychotherapy literature. Research in surgery and psychotherapy share other similarities beyond having to account for practitioner expertise. There is the issue of blindness—hard to achieve for practitioners with experience, together with “communicators,” and not only by people who studied communication skills who have never had to tell anybody that they have cancer and are dying, or let a family know that a patient has died. The impact of this is greater than most people can imagine, and I think poor communication on those subjects often reflects the inability of the doctor to deal with his or her own feelings. The same goes for communicating with colleagues. In my hospital, emergency departments are now filmed in major trauma cases, and the people on the floor are actually the ones being filmed. Evaluation is then done by the surgeons, together with a psychologist.

Communication skills are essential, but not at the expense of medical students’ pre-clinical and clinical curriculum. The target groups should therefore be senior house officers and specialist registrars.

Old docs and new tricks Seasoned doctors may be better than young doctors at some things Editor—Spurgeon reports that the doctors’ standards of care drop with years in practice.1 When I began clinical practice in the late 1980s I thought that one key to being a “good doc” was keeping up with the latest drugs and technologies. I was dismayed to see seasoned colleagues who were slow to change. I then saw many new drugs get pulled from the market (rofeconob is not the first non-steroidal anti-inflammatory drug to be withdrawn) and various medical fads come and go. Evidence based medicine appropriately sheds light on the public evidence available to support most things that physicians do.

Armed with this keener analytical approach, I came to realise that most claims of benefit are greatly exaggerated compared with absolute incremental changes and that most patients are not like trial subjects. Although an intervention might benefit the patient who sits before me, I suspect that seasoned doctors are better than their junior colleagues at some things, and worse at others. Maybe the ability to see the big picture, diagnostically and therapeutically, is enhanced by experience. Meanwhile the emphasis on the newest treatment detail might wane. Perhaps that is a reason why I have conflicting opinions about whether doctors get better with time.

Senior house officers (SHOs) and registrars should be doing the training. We do the damage in our “bad news” talks. We know what we are talking about, and we do it daily. We should be the ones filmed on camera and evaluated. This should be done with clinicians with experience, together with “communicators,” and not only by people who studied communication skills who have never had to tell anybody that they have cancer and are dying, or let a family know that a patient has died. The impact of this is greater than most people can imagine, and I think poor communication on those subjects often reflects the inability of the doctor to deal with his or her own feelings.

The same goes for communicating with colleagues. In my hospital, emergency departments are now filmed in major trauma cases, and the people on the floor are actually the ones being filmed. Evaluation is then done by the surgeons, together with a psychologist.

Communication skills are essential, but not at the expense of medical students’ pre-clinical and clinical curriculum. The target groups should therefore be senior house officers and specialist registrars.

Efficiency is important Editor—in British general practice, where everyday demand exceeds capacity, the efficient general practitioner is king. That is one thing that experience should bring. If all general practitioners followed every guideline the system would collapse, and although a few patients would have exemplary care, many would have no care at all as they would just not get seen because they would find the wait intolerable. Perhaps this is what happens now in secondary care, where care delivered is often very good but access is less and less. A perceived practice is often developed for a “one issue patient.” Reality means multi-issues, patients who themselves have limited ability to follow all the investigation and “treatment” recommended by the single issue academic establishment. Many indications for treatment are immediately met with contraindications. Experience allows general practitioners to cut back on too much excess investigation and treatment while still striving to meet the guidelines.

Protecting the patient from the iatrogenic harm of excess health care used to be a core skill of the general practitioner. Is this being taken away from us as well? A system that fails to value the soft end points and often efficient and effective care that experience brings will have to restructure to meet the demand and that inevitably will lead to a hugely expanded system with resource implications. I am not disputing the findings of the paper reported by Spurgeon, that the standard of care may drop with years spent in practice, but the immediate common sense logic of the hypothesis and conclusions make me advise to proceed down this route with caution. Being a doctor is already a difficult job. Being advised that all your thoughtful patient experience has actually made you a worse doctor is demotivating. Perhaps experienced doctors and patients would have a different set of criteria about what good care is?
