Received 28 November 2003/Returned for modification 21 January 2004/Accepted 19 February 2004

Fulminant meningococcal sepsis has been termed the prototypal lipopolysaccharide (LPS)-mediated gram-negative septic shock. Systemic inflammation by activated complement and cytokines is important in the pathogenesis of this disease. We investigated the involvement of meningococcal LPS in complement activation, complement-dependent inflammatory effects, and cytokine or chemokine production. Whole blood anticoagulated with lepirudin was stimulated with wild-type *Neisseria meningitidis* H44/76 (LPS+), LPS-deficient *N. meningitidis* H44/76ΔpxA (LPS−), or purified meningococcal LPS (NmLPS) at concentrations that were relevant to meningococcal sepsis. Complement activation products, chemokines, and cytokines were measured by enzyme-linked immunosorbent assays, and granulocyte CR3 (CD11b/CD18) upregulation and oxidative burst were measured by flow cytometry. The LPS+ and LPS− *N. meningitidis* strains both activated complement effectively and to comparable extents. Purified NmLPS, used at a concentration matched to the amount present in whole bacteria, did not induce any complement activation. Both CR3 upregulation and oxidative burst were also induced, independent of LPS. Interleukin-1β (IL-1β), tumor necrosis factor alpha, and macrophage inflammatory protein 1α production was predominantly dependent on LPS, in contrast to IL-8 production, which was also markedly induced by the LPS− meningococci. In this whole blood model of meningococcal sepsis, complement activation and the immediate complement-dependent inflammatory effects of CR3 upregulation and oxidative burst occurred independent of LPS.

Invasive disease caused by the gram-negative bacterium *Neisseria meningitidis* is a life-threatening infection in children and young adults. Meningococcal septic shock (or fulminant meningococcal sepsis [FMS]), the prototype of overwhelming gram-negative sepsis, is feared especially because it is able to cause devastating disease with a high case fatality rate. The pathogenic mechanisms leading to FMS are thought to be the uncontrollable growth of meningococci in the circulation, resulting in a massive activation of diverse inflammatory systems, such as the complement system, the cytokine network, and the coagulation cascade (6, 35).

In FMS, high lipopolysaccharide (LPS) levels are correlated with an increased bacterial load, high levels of pro- and anti-inflammatory cytokines, increased complement activation, the induction of intravascular coagulation, and a poor outcome. Therefore, meningococcal LPS is regarded as the principal bacterial pathogenic element during FMS (3).

The complement cascade plays a dual role in the pathogenesis of meningococcal infections. A complement deficiency predisposes some individuals to meningococcal infection (10, 17, 28), but on the other hand, with FMS, extensive complement activation is correlated with severe disease and a poor outcome (4, 16). Thus, the complement system plays an important role in the first line of defense against meningococcal infection, whereas massive activation of the complement system contributes to the development of shock.

Complement is activated on the meningococcal surface by one or more of the three initial complement-activating pathways, i.e., the classical, the lectin, and the alternative pathways (Fig. 1). After the activation of complement factor 3 (C3) by any of these pathways, a C5 convertase is formed, which cleaves the pivotal C5 molecule into C5a and C5b. C5b is the initial molecule in the formation of the terminal C5b-9 complement complex (TCC). Membrane-associated TCC, also designated the C5b-9 membrane attack complex, leads to lysis of the bacterium, whereas C5a is a potent anaphylatoxin (24). Experimentally, the role of the complement system in inflammation by *N. meningitidis* and *Escherichia coli* was recently given more emphasis by our observation that granulocyte CR3 (CD11b/CD18) upregulation and the formation of reactive oxygen species in human whole blood, key elements in the induction of vascular damage during sepsis, are highly dependent on C5a (22, 29).

Recent in vitro studies suggested that components of *N. meningitidis* other than LPS may also contribute to the inflammatory response of the host. Using a meningococcal mutant that was deficient for LPS in the outer membrane, we and others have shown that proinflammatory cytokines can be induced independent of LPS in cultured human cells (27, 30, 34).

In addition, we showed that purified meningococcal LPS (NmLPS) is a poor activator of complement, whereas experiments with outer membrane vesicles that were depleted of or completely lacking LPS suggested that non-LPS components in

Cocci were grown overnight on Kellogg's medium and resuspended in Hank's to mostly short-chain, saturated fatty acids (31). LPS-deficient mutant is similar to that of the wild-type strain; shown by Steeghs et al., the expression level of the integral outer membrane protein, C4bc reflects both classical and lectin pathway activation, and C3bbBp reflects alternative pathway activation. TCC is an activation product of the final common and terminal pathways.

The bacterial outer membrane are the principal complement activators in a whole blood model (1).

For the present study, LPS-containing N. meningitidis, LPS-deficient N. meningitidis, and purified meningococcal LPS were used in a human whole blood model of meningococcal sepsis to determine the role of LPS in complement activation, the complement-dependent inflammatory processes of CR3 upregulation and oxidative burst, and cytokine production.

For the present study, LPS-containing N. meningitidis (LPS) was used for the study of N. meningitidis-infected inflammatory protein 1α (MIP-1α) was processed as described for complement activation, but the incubation time was increased to 2 h.

Enzyme immunoassays. Complement activation was measured in plasma by enzyme immunoassays based on MAbs that were highly specific for the activation products; the native, nonactivated components did not interfere in the assays. Activation of the three initial pathways was selectively detected.

(i) Clrs–C1inh complexes. Activation of the classical complement pathway was determined as described previously (12). Clrs–C1 inhibitor (Clrs–C1inh) complexes were measured by using MAbs that were highly specific for the detection antibody. The standard was identified in a forward scatter-side scatter plot by their typical patterns.

(ii) C4bc. Activation of the classical and lectin pathways was determined by an assay using a MAb specific for a neoepitope exposed in activated C4 (42). The C4bc assay detects the sum of the activation products C4a, iC4b, and C4c.

(iii) C3bbBp complexes. Activation of the alternative pathway was detected by measuring the alternative convertease C3b-Bb-properdin (C3BbBn), as recently described (22). The capture antibody used was an antiproperdin antibody, and the detection antibody was a polyclonal anti-C3 antibody. The standard was normal human serum activated with zymosan and defined to contain 1,000 AU/ml.

(i) TCC. Activation of the terminal pathway was quantified by using MAb aE11, specific for C9 incorporated in the fluid-phase SC5b-9 complex, as described previously (23). The same standard was used, with a biotinylated anti-C9 antibody used as the detection antibody. Human serum activated with zymosan was used as the standard.

MATERIALS AND METHODS

Equipment and reagents. All materials used in the stimulation experiments were endotoxin-free. The polypropylene tubes used were either Nunc cryotubes (Nalgene Nunc, Roskilde, Denmark) or Falcon tubes (Becton Dickinson, Franklin Lakes, N.J., USA). Phosphate-buffered saline (PBS) was produced in the laboratory, Dulbecco's medium was obtained from Invitrogen Corporation (Paisley, Scotland), and leupirudin (Refludan) was purchased from Hoechst (Frankfurt am Main, Germany). Flow cytometry was performed with a FACS Calibur instrument (Becton Dickinson San Jose, Calif.), and optical densities were determined with an MRX microplate reader (Dynex Technologies, Denkendorf, Germany).

Bacterial strains. N. meningitidis H44/76 (LPS−) is an isolate from a patient with invasive meningococcal disease (18). This strain is the production strain for the Norwegian group B OMV vaccine and is an international reference strain (11), serologically classified as B:15:P1.7,16, immunotype L3,7,9, as determined by the use of anti-LPS monoclonal antibodies (MAbs) in a dot blotting assay for immunotyping (40). The LPS-deficient strain N. meningitidis H44/76puc4 (LPS−) is a viable inogenic mutant of strain H44/76 that lacks LPS in the outer membrane and was a kind gift from Peter van der Ley and Liana Steeghs (Dutch Vaccine Institute, Bilthoven, The Netherlands). It was constructed by insertional inactivation of the lpcA gene, which is essential for the first committed step of biosynthesis of LPS, as described by Steeghs et al. (32). For the present study, batch suspensions of H44/76puc4 were tested and showed no reactivity in a Luminas amebocyte lysate (ALAL) assay, a highly specific and sensitive test for LPS. As shown by Steeghs et al., the expression level of the integral outer membrane proteins by the LPS-deficient mutant is similar to that of the wild-type strain; however, the outer membrane phospholipid composition is altered, with a switch to mostly short-chain, saturated fatty acids (31). LPS-deficient mutant meningococci were grown overnight on Kellogg's medium and resuspended in Hank's balanced salts solution (Invitrogen). Bacteria were heat inactivated at 60°C for 40 min. The concentration of the bacteria was determined by measuring the optical density at 630 nm. NmLPS were isolated from strain H44/76 by phenol-water extraction (41) followed by DNase, RNase, and proteinase K treatment. The batch of LPS used for this study was previously shown to be highly reactive in the LAL and a potent inducer of cytokine production (29). Quantification of the amount of LPS in LPS− N. meningitidis H44/76 bacteria was performed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) followed by silver staining of LPS. The LPS level was determined by digital scanning, with purified H44/76 LPS used as the standard (30, 33).

Whole blood model. A recently developed whole blood model for the study of N. meningitidis was used in this study (29). The model is based on anticoagulation with lepirudin, a recombinant hirudin which is a highly specific thrombin inhibitor that minimally influences complement activation or cytokine production. Whole blood from healthy, adult volunteers was collected in polypropylene tubes containing lepirudin (50 μg/ml final concentration). Informed consent was obtained from all donors prior to the experiments, and the human experimentation guidelines of the local ethics committee were followed in conducting the research. Immediately after being drawn, the whole blood (1 ml) was incubated with the stimulants (0.1 ml).

For the determination of granulocyte CR3 (CD11b/CD18) expression and oxidative burst, samples were incubated for 30 min at 37°C in a water bath, followed by immediate processing for flow cytometry.

For the detection of complement activation, samples were incubated for 1 h at 37°C in a Coulter mixer (Coulter, Lyndon, Eng). Supplement activation was stopped by the addition of EDTA to a final concentration of 20 mM, after which samples were centrifuged at 1,400 × g for 10 min. The plasma was collected and stored at −70°C until samples were assayed in one batch.

Samples for the measurement of tumor necrosis factor alpha (TNF-α), interleukin-1β (IL-1β), IL-8, and macrophage inflammatory protein 1α (MIP-1α) were processed as described for complement activation, but the incubation time was increased to 2 h.

Oxidative burst. Oxidative burst was measured by using a commercially available Burst-test kit (Orpegen Pharma, Heidelberg, Germany). After incubation as described above, samples were treated according to the manufacturer's instructions and assayed by flow cytometry. Granulocytes were identified in a forward scatter-side scatter plot by their typical patterns.

C3 (CD11b/CD18) expression. After being incubated as described above, cells were washed once in sterile PBS and fixed with 0.5% (vol/vol) paraformaldehyde in an equal volume of PBS for 4 min at 37°C. Cells were stained with an anti-CD11b-PE or isotype control (λ2a) (Becton Dickinson) antibody for 15 min at room temperature. An anti-CD14-FITC (Becton Dickinson) antibody and the nuclear dye LDS-751 (Molecular Probes Inc., Eugene, Oreg.) were used to discriminate granulocytes in washed whole blood.

Enzyme immunoassays. Complement activation was measured in plasma by enzyme immunoassays based on MAbs that were highly specific for the activation products; the native, nonactivated components did not interfere in the assays. Activation of the three initial pathways was selectively detected.

(i) Clrs–C1inh complexes. Activation of the classical complement pathway was determined as described previously (12). Clrs–C1 inhibitor (Clrs–C1inh) complexes were measured by using MAbs that were highly specific for the detection antibody. The standard was identified in a forward scatter-side scatter plot by their typical patterns.

(ii) C4bc. Activation of the classical and lectin pathways was determined by an assay using a MAb specific for a neoepitope that is exposed in activated C4 (42). The C4bc assay detects the sum of the activation products C4a, iC4b, and C4c.

(iii) C3bbBp complexes. Activation of the alternative pathway was detected by measuring the alternative convertease C3b-Bb-properdin (C3BbBp), as recently described (22). The capture antibody used was an antiproperdin antibody, and the detection antibody was a polyclonal anti-C3 antibody. The standard was normal human serum activated with zymosan and defined to contain 1,000 AU/ml. Both the MAb for this assay and Kok-12 were a kind gift from C. E. Hack, Department of Immunopathology, Sanquin Research, Amsterdam, The Netherlands.

(iv) TCC. Activation of the terminal pathway was quantified by using MAb aE11, specific for C9 incorporated in the fluid-phase SC5b-9 complex, as described previously (23). The same standard was used, with a biotinylated anti-C9 antibody used as the detection antibody. Human serum activated with zymosan was used as the standard.

FIG. 1. Schematic overview of the complement system. Boxes indicate specific complement activation products measured in the present study and their relation to specific complement activation pathways. Clrs–C1inh complexes reflect classical pathway activation, C4bc reflects both classical and lectin pathway activation, and C3bbBp reflects alternative pathway activation. TCC is an activation product of the final common and terminal pathways.

vols. 2004 LPS-INDEPENDENT COMPLEMENT ACTIVATION 3345
were considered statistically significant.

total complement activation (Fig. 1).

C4bc (classical and lectin pathways) and C3bBbP (alternative pathway) complexes were used to determine the initial complement activation. The lower limit of detection was 0.25 endotoxin units/ml.

E. coli as a reference. The lower limit of detection was 0.25 endotoxin units/ml.

FIG. 2. Complement activation by LPS+ and LPS− N. meningitidis and by purified NmLPS. The results are for the formation of C1rs-C1inh (classical pathway), C4bc (classical and lectin pathways), C3bBbP (alternative pathway), and TCC (final common pathway) after the stimulation of lepirudin-treated human whole blood for 1 h with LPS+ (diamonds) or LPS− (squares) N. meningitidis or purified NmLPS (circles). The x axes are calibrated for the numbers of LPS+ N. meningitidis cells as well as the amounts of NmLPS that are present in the bacteria, according to SDS-PAGE analysis. Medians and upper quartiles are presented from four separate experiments. *, P < 0.05; **, P < 0.01, by two-way ANOVA. Dashed lines indicate baseline complement activation.

An overview of the complement activation markers measured is illustrated in Fig. 1.

Cytokines and chemokines. Commercially available enzyme-linked immunosorbent assay (ELISA) kits were used according to the manufacturers’ instructions to quantify TNF-α, IL-1β, IL-8 (Duo Set ELISA development system [R&D Systems, Minneapolis, Minn.] for all three), and MIP-1α (MIP-1α Cytoscreen [Biosource International, Camarillo, Calif.]). All cytokine and chemokine levels were measured by ELISA.

Statistics. A two-way analysis of variance (ANOVA) for repeated measures was used to test the data for statistically significant differences. P values of <0.05 were considered statistically significant.

RESULTS

Complement activation by LPS+ and LPS− N. meningitidis or purified NmLPS. Assays for C1rs-C1inh (classical pathway), C4bc (classical and lectin pathways) and C3bBbP (alternative pathway) complexes were used to determine the initial complement activation pathways, whereas soluble TCC, the final product of the terminal pathway, was used as an indicator of total complement activation (Fig. 1).

The amount of LPS per 10^6 N. meningitidis cells was estimated by SDS-PAGE analysis; this showed that 10^6 bacteria contained approximately 5 ng of LPS. In Fig. 2 and 3, the x axes are calibrated for the numbers of LPS+ N. meningitidis cells as well as the amounts of LPS that are present in the bacteria. In this way, the activities of the bacteria and purified LPS can be compared quantitatively.

The levels of the markers of initial pathway activation, C1rs-C1inh, C4bc, and C3bBbP, as well as that of TCC from the terminal pathway, were all increased from the baseline after stimulation with LPS+ or LPS− N. meningitidis (Fig. 2). The activation of initial complement activation products was seen at concentrations of 10^6 meningococci/ml or higher, which correspond to approximately 5 ng of NmLPS or more/ml. In contrast, purified NmLPS did not induce complement activation at concentrations up to 1,000 ng/ml. The combination of purified NmLPS and LPS+ N. meningitidis induced complement activation to a similar extent as LPS+ or LPS− N. meningitidis (not shown). These data indicate that complement activation by N. meningitidis in human whole blood occurs independently of the LPS outer membrane component.

Granulocyte CR3 upregulation and oxidative burst by LPS+ and LPS− N. meningitidis or purified NmLPS. Recently, the CR3 upregulation and oxidative burst induced by N. meningitidis in granulocytes were shown to be complement dependent (29). Therefore, we investigated the role of LPS in these processes.

Both LPS+ and LPS− N. meningitidis at concentrations of 10^6/ml induced marked granulocyte CR3 upregulation and oxidative burst. The addition of purified NmLPS to LPS-deficient N. meningitidis did not influence the CR3 upregulation or oxidative burst (not shown). Notably, purified NmLPS did not induce significant CR3 upregulation or oxidative burst at concentrations up to 1,000 ng/ml (Fig. 3). These results indicate that the upregulation of CR3 expression and the oxidative burst in whole blood granulocytes after stimulation with N. meningitidis are not dependent on NmLPS.

Cytokine and chemokine induction by LPS+ and LPS− N. meningitidis. Cytokine and chemokine induction in a human whole blood model of meningococcal sepsis was assessed after...
ment activation and the complement-dependent in
the absence of LPS (Fig. 4).

No cytokine or chemokine production was seen in this whole
blood for 2 h with LPS\(^+\) (diamonds) or LPS\(^-\) (squares) \(N.\) meningitidis.
Mean cytokine or chemokine production levels from three separate
experiments are presented. *, \(P < 0.05\), by two-way ANOVA.

2 h of incubation with LPS\(^+\) or LPS\(^-\) \(N.\) meningitidis (Fig. 4).
No cytokine or chemokine production was seen in this whole
blood model in the absence of a stimulus. LPS\(^+\) \(N.\) meningitidis
was a potent inducer of IL-1\(\beta\), TNF-\(\alpha\), IL-8, and MIP-1\(\alpha\) production, as it was able to induce cytokine and chemokine
production at concentrations higher than 10\(^6\) meningococci/ml.
IL-1\(\beta\), TNF-\(\alpha\), IL-8, and MIP-1\(\alpha\) production by LPS\(^-\) meningococci was significantly reduced compared to that by LPS\(^+\) \(N.\) meningitidis (\(P < 0.05\) for all cytokines and chemokines mea-
sured). However, marked IL-8, and to a lesser extent, TNF-\(\alpha\) and MIP-1\(\alpha\) production was also induced by LPS\(^-\) \(N.\) menin-
gitidis, suggesting that these mediators can also be induced in
the absence of LPS (Fig. 4).

**DISCUSSION**

The principal finding of the present study was that comple-
ment activation and the complement-dependent inflammatory
events of CR3 upregulation and oxidative burst are independ-
ent of LPS in a whole blood model of meningococcal sepsis.

The construction of the LPS-deficient meningococcal mut-
ant H44/76DerA has made it possible to study the relative
importance of the LPS moiety of a gram-negative bacterium in
diverse inflammatory processes (32). We used LPS-deficient \(N.\) meningitidis to assess the involvement of meningococcal LPS in
complement activation, complement-dependent inflammatory
effects, and cytokine or chemokine production in a human
whole blood model of meningococcal sepsis. The lack of reac-
tivity of the LPS\(^-\) strain in a LAL assay confirmed the absence
of LPS in the batch used for the experiments. The estimate that
10\(^6\) LPS\(^+\) meningococci contained approximately 5 ng of me-
ningococcal LPS was in line with previous estimations (2, 30).

\(N.\) meningitidis is exclusively a human commensal or patho-
gen, and none of the animal models available accurately sim-
ulate FMS. Therefore, we used an in vitro experimental system
approaching, as closely as possible, the human in vivo situation
(22, 29). The principle of this model is to keep all ambient
inflammatory systems intact so that they can be activated and
mutually interact but still to avoid coagulation. Because most
anticoagulants, such as EDTA, citrate, and heparin, interact
with critical steps in the inflammatory network, this model uses
the highly specific thrombin inhibitor lepirudin, a recombinant
hirudin analogue, as an anticoagulant. CR3 upregulation and
oxidative burst were found to be induced to a similar extent by
live or heat-inactivated bacteria in this model. Since these
processes are highly complement dependent, this indicates that
complement activation is also not affected by inactivation of the
bacteria. Therefore, heat-inactivated bacteria were used
because of practical considerations, as live meningococci con-
stitute a significant health hazard (29).

LPS is present in solution in the form of micellar structures,
which is quite distinct from its organization when it is present
in the outer membrane. Hypothetically, the physicochemical
presentation of LPS could affect the complement-activating
ability, favoring membrane-bound LPS as the stronger com-
plement activator. However, the observation that LPS-contain-
ing meningococci activate complement to a similar extent as
LPS-deficient meningococci suggested that this is not the case,
as did the absence of an increase in the complement-activating
ability when isolated LPS was added back to the LPS-deficient
strain. This is supported by a previous study in which neisserian
outer membrane vesicles (OMVs) containing LPS were equip-
ment to OMVs deficient for LPS (1).

Complement activation by LPS\(^+\) or LPS\(^-\) \(N.\) meningitidis
was seen at concentrations of 10\(^3\)/ml or higher. This is a con-
centration of meningococci that is frequently found during
FMS (3, 13); 10\(^6\) LPS\(^-\) \(N.\) meningitidis cells contain approxi-
mately 5 ng of LPS. In contrast, complement was not activated
by purified LPS at concentrations up to 1,000 ng/ml. This
suggests that during meningococcal sepsis, complement activa-
tion is not induced by LPS, but by other constituents of \(N.\) meningitidis.

Members of our laboratory previously reported that the up-
regulation of CR3 and the induction of oxidative burst in
granulocytes in this whole blood model are dependent on com-
plement activation (22, 29). When complement is activated,
C5a is formed, and this anaphylatoxin reacts with the C5a
receptor on granulocytes and monocytes to induce the upregu-
lation of CR3. CR3 is the principal receptor involved in the
phagocytosis of C3b-coated bacteria, and when upregulated, it
will enhance phagocytosis of the bacteria and in this way stim-
ulate the oxidative burst process. Our results indicate that CR3
expression and oxidative burst are mediated by non-LPS com-
ponents of \(N.\) meningitidis.

It is commonly accepted that LPS extracted from diverse
gram-negative bacteria activates complement readily via clas-
sical and alternative pathway-dependent mechanisms (25, 38).
In addition, LPS has been shown to be able to upregulate CR3
expression and to prime neutrophils for oxidative burst (8, 9,
19, 21). However, for the experiments presented in these stud-
ies, very high concentrations of LPS were applied (>5 to 10 μg/ml), incubation times of longer than 30 min were employed for granulocyte activation, or isolated cell cultures or plasma were used. In addition, it was recently shown that a contaminating substance of commercially available LPS is, at least in part, responsible for the upregulation of neutrophil responses (20). We claim that the conditions used in our study more closely resemble the in vivo situation than those used in previous studies. In our model, purified NmLPS was tested in whole blood at concentrations that are relevant for the situation encountered during FMS. The relatively short incubation times mimic the function of the complement cascade system, the components of which are present in plasma and able to be immediately activated by an invading pathogen, in this way avoiding the contribution of activation processes secondary to other inflammatory events.

We propose that the observed weak complement-activating property of NmLPS is not specific for this type of LPS, as it has a relatively short saccharide side chain, but that other types of LPS are also weak complement activators at relevant concentrations. Preliminary data from our laboratory suggest that this is the case for E. coli LPS in the same in vitro model. In addition, in primate models, complement is not activated after E. coli LPS infusion, but after whole E. coli cell infusion, marked complement activation occurs within 15 min (15, 37). Also, in a human endotoxemia model, no complement activation is observed, whereas significant cytokine production, endothelial cell activation, and activation of the coagulatory and fibrinolytic systems are found (36a).

The bacterial components that are involved in the activation of complement, the upregulation of CR3 expression, and oxidative burst remain elusive and will be subjected to further investigation. It was previously reported that OMVs isolated from LPS-deficient N. meningitidis induce substantial complement activation (1). This suggests that the non-LPS components that induce complement activation reside in the outer membrane. The lectin pathway seems to be an important player in complement activation by meningococci when they are grown on Kellog’s medium and studied in the whole blood model (1, 29). Since mannose-binding lectin binding to the bacteria occurs via the outer membrane proteins porin and opacity protein (OpA) independently of LPS (9a), it is reasonable to suggest that the porins and OpA are responsible, at least in part, for the observed complement activation and subsequent CR3 upregulation and oxidative burst.

The proinflammatory cytokines TNF-α and IL-1β are primary cytokine mediators during meningococcal sepsis, whereas IL-8 and MIP-1α are important chemotactic proteins that are important for pathogenesis (14, 36, 39). We found that LPS– N. meningitidis induced marked IL-8, and to a lesser extent, TNF-α and MIP-1α production in the whole blood model, indicating that bacterial components other than LPS are also proficient at inducing cytokine or chemokine production. However, LPS + N. meningitidis was more potent in the induction of these proinflammatory mediators, in particular TNF-α and MIP-1α, indicating that LPS is an important factor involved in the regulation of these processes, which is in agreement with previous reports (27, 30, 34). It is tempting to speculate that the observed LPS-independent induction of IL-8, and possibly also TNF-α and MIP-1α, is mediated or potentiated by the activation of complement factor C5a, as has been suggested previously (7, 22, 26).

We conclude that complement activation occurs independently of the LPS moiety of N. meningitidis. Therefore, CR3 upregulation and oxidative burst, previously shown to be highly complement dependent, are also independent of LPS. Cytokine and chemokine production can be induced via LPS-dependent as well as LPS-independent mechanisms.

ACKNOWLEDGMENTS

We thank Anne Pharo, Gunni Ulvund, Hilde Fure, Karin Bolstad, and Berit Nyland for their excellent technical assistance. Peter van der Ley and Liana Steeghs are thanked for supplying the LPS-deficient meningococcal strain.
