(Dated: February 26, 2004)

Phonon excitations of fractional quantum Hall states at filling factors $\nu = p/q$ ($q$ is an odd-integer) [1, 2]. In the last decade this fractional quantum Hall (FQH) effect was very effectively described in the framework of Composite Fermions (CFs) [3]. At a fractional filling factor with even denominator, $\nu = 1/2$, these quasiparticles are formed by attaching an even number $2m$ of flux quanta $\phi_0$ to each electron, i.e. two flux quanta at $\nu = 1/2$. Their effective mass $m^*$ is originating from the Coulomb interaction [4].

The ground state of a 2DES at a fractional filling factor $\nu = p/q$ is a collective wave function [2] with finite wave-vector collective excitations [5, 6] directly accessible by e.g. Raman techniques [7, 8], photoluminescence [9] or phonon absorption experiments [10, 11]. In a simple picture these excitations originate from the level structure of CFs in an effective magnetic field, $B_{\text{eff}} = B - B_z$ ($\nu = 1/2$), with an effective (integer) filling factor, $p = \frac{1}{2\nu - 2m}$ [3]. The levels can then be described as spin-split Landau levels of CFs and, therefore, excitations can be interpreted as either Landau level transitions or spin-excitations.

In this Letter we use phonons to probe the FQH excitation spectrum at filling factors $\nu = 1/3, 2/5, 4/7, 3/5, 2/3, 4/3,$ and $5/3$ when varying the electron densities in the same sample over a wide range. At a given filling factor nearly all gaps measured show a square-root dependence on the magnetic field, strongly suggesting that we probe Landau level transitions of CFs. All these data are described by one single fit parameter related to the CF effective mass. Surprisingly, the gap at $\nu = 2/3$ displays a linear field dependence, rather related to a spin transition forbidden for phonon excitations. This observation is a clear hint that the $2/3$-ground-state is not fully spin-polarized in high $B$-fields and that a strict separation between spin transitions and CF Landau-level transitions is no more possible.

Our sample consists of a high-mobility AlGaAs/GaAs-heterojunction grown on a 2 mm thick GaAs wafer. On the front side containing the 2DES we patterned a $w = 90 \mu m$ wide meander extending over a total length $l = 10 mm$ on an area $A = 1 \times 1 mm^2$. The huge aspect ratio $l/w = 111$ maximizes the $p_{xx}$-contribution to the two-terminal resistance and thereby allows to measure smallest changes in $p_{xx}$. The Ohmic contacts to the 2DES are placed at the edges of the sample far away from the meander to avoid any phonon interactions with the contacts. We took great care that the contact resistances ($< 10 \Omega$) only play a negligible role in the measured two-terminal resistance. Using the persistent photoconductivity we varied the electron concentration in several steps from $n = 0.89 \times 10^{12} m^{-2}$ (mobility $\mu = 102 m^2/Vs$) to $n = 1.50 \times 10^{12} m^{-2}$ (mobility $\mu = 193 m^2/Vs$).

The sample is mounted on the tail of a dilution refrigerator in a superconducting magnet with maximum fields up to 13 T and connected to high frequency coaxial cables. Great care was taken to assure a proper thermal anchoring of the cables. We achieve a 2DES temperature $T_{2DES} \lesssim 100 mK$ for a cryostat base temperature of 75 mK.

The experimental setup is shown schematically in Fig. 1a: A thin constantan film acting as a phonon emitter is placed on the polished back side of the sample. By passing a short current pulse during a time $\tau_H$ through this heater, non-equilibrium phonon pulses are created at the heater-GaAs interface. They are characterized by a black-body spectrum at a temperature $T_H = (P_H/\sigma A_H + T_0^4)^{1/4}$, where $A_H$ is the heater area, $P_H$ is the power dissipated in the heater, $\sigma = 524 W/m^2 K^4$ is the acoustic mismatch constant between constantan and GaAs, and $T_0$ is the GaAs lattice temperature [12]. When entering the GaAs, the non-equilibrium phonons travel ballistically through the 2 mm-thick substrate. Af-
number ofphonons emitted in the pulse is n = 0.89 \times 10^{15} \text{ m}^{-2}.

In a first set of experiments, we calibrate the relative specific heat of the 2DES at given fractional filling factor. The maximum 2DES temperature on the first ballistic phonon peak, $T_1$ (see Fig. 1d), is measured as a function of the 2DES base temperature $T_0$, with a fixed duration and a constant amplitude of the heater pulse. Since all the $T_0$ used are distinctively lower than the energy gaps at these filling factors we always deal with a situation where the quasiparticle ground states are almost full and their excitations are almost empty. As a consequence, the relative proportion of phonons absorbed is independent from $T_0$, and we can approximate $r(T, T_1) \rightarrow r_0$. Integrating Eq. (1) over the pulse length with these assumptions, we get:

$$\int_{T_0}^{T_1} C(T) \,dT = r_0 P_{H1} \tau_H$$

Using the mean value theorem for this integral equation we can determine the relative specific heat $C(T)/r_0$ of the 2DES from our set of experiments where we measured $T_1$ for fixed heater power and varying $T_0$. As a consistency check we performed the same set of experiments with different heater powers and find a very comparable temperature dependence of $C(T)$.

In Fig. 2a the measured relative specific heats, $C(T)/r_0$, are shown exemplarily for filling factors $\nu = 2/3$ and 2/5. We should note that we cannot determine the absolute value of $C(T)$ due to the unknown absorption

(b) Steady-state calibration of the 2DES resistance at $\nu = 2/3$ for $n = 0.89 \times 10^{15} \text{ m}^{-2}$.

(c) Phonon signal for the same $\nu$ and $n$ after emitting $T_H = 2.09 \text{ K}$ phonons during $\tau_H = 10 \text{ ns}$ at $t = 0$. The 2DES was excited from a base temperature $T_0 = 75 \text{ mK}$.

(d) 2DES temperature versus time as deduced from raw phonon signal curve (c) using the calibration (b).
coefficient $r_0$ ($0 < r_0 < 1$). The lines shown in Fig. 2a are fits to the theoretical predictions for the specific heat of a 2DES $C_{\text{2DES}} \propto \frac{1}{T} e^{-\Delta c/T}$ [14] plus a small empirical constant, taking into account an additional contribution to $C(T)$ possibly resulting from a finite (thermodynamic) density of states inside the excitation gap [11].

In a second set of phonon absorption experiments we can now determine the energy gaps at fractional filling factors. This time, the heater temperature $T_H$ is varied for a fixed base temperature $T_0$. By increasing $T_H$, the number of phonons for every wavelength is increased. Since the major contribution to the phonon absorption is predominantly due to excitations around a gap $\Delta$, the total energy absorbed by the 2DES increases as

$$E_{\text{abs}} \propto \frac{1}{\exp(\Delta/T_H)} - 1$$

(3)

The absorbed phonon energy, $E_{\text{abs}} = r(T, T_H) P_H T_H$, as a function of $T_H$ is deduced from the measured $T_1$ and $T_0$ by integrating Eq. (1) using the previously determined specific heat. Again, the emission term is neglected for the short time scales considered. In Fig. 2b we show results for filling factors $\nu = 2/3$ and 2/5. The gap values are obtained by averaging over several experiments using different heater powers and base temperatures. All the individual gaps measured are within $\pm 10\%$ of the average value. The solid lines in Fig. 2b show fits using Eq. (3) and indeed, the experimental data match a model with phonon excitation across a single energy gap $\Delta$.

Using such an elaborated series of calibrations we can now investigate in detail the excitation gaps. As listed in Table I, we have measured the gaps for eight different electron concentrations at filling factors $\nu = 2/3$, 2/5, and 1/3 up to the highest magnetic fields accessible in our magnet. These filling factors all showed well developed minima for all the concentrations used. Additional filling factors $\nu = 4/3, 5/3, 3/5$ and 2/7 are only clearly pronounced for the highest electron concentration and, accordingly, phonon gaps were only measured in sample #8 for these filling fractions.

All gaps measured at various filling factors and electron concentrations are compiled in Fig. 3a. For comparison, we also show the energy gaps deduced from activated transport measurements [17] in Fig. 3b. In order to discuss these results for different filling factors $\nu$ we describe them within the CF picture [3], where the FQH filling factors $\nu = \frac{p}{p+1}$ are mapped to integer CF filling factors $p$. The energy levels for $|p|$ filled CF Landau levels can then be written [15] as:

$$E_{ns}(p) = (n + \frac{1}{2})\hbar \omega_c^*(p) + sg^* \mu B$$

(4)
Here the CF cyclotron energy is given purely by the Coulomb interaction and thus follows the form $\hbar \omega_c^* = \hbar c B/(m^*(2p \pm 1))$ with a CF mass $m^* = m_e \alpha \sqrt{B/T}$ [16].

Since phonons carry no spin we expect that, in a phonon absorption experiment, the lowest lying excitations of a CF state $p$ are Landau level transitions from $n$ to $n+1$ with the same spin $s$. The corresponding energy gap $\hbar \omega_c^*(p)$ can now be adjusted to our data by one single dimensionless mass parameter $\alpha$. In Fig. 3 the fits of such Landau level transitions to all the data at $\nu = 1/3, 2/5, 4/7, 3/5, 4/3,$ and $5/3$ are shown yielding $\alpha = 0.158$ (±0.006) (dotted lines). Here, $\nu = 4/3 = 1 + 1/3$ and $5/3 = 1 + 2/3$ are treated as $1/3$ respectively $2/3$ plus one inert fully occupied Landau level. The experimentally determined CF mass parameter $\alpha$ is in astonishing agreement with the theoretical predictions in Eq. (1) of Ref. 16.

Compared to all phonon gaps measured at the above mentioned filling factors, the phonon absorption data at filling factor $2/3$, are distinctively different: The measured excitation gaps can in no way be described with the square-root dependence of CF Landau level excitations. They rather show a linear dependence, $\Delta_{2/3} \propto (B - B_p)$, strongly suggesting that they are related to a spin gap, which is normally not directly accessible by phonon excitations. Here $B_p \approx 2.8$ T is the field where the $2/3$ state changes from a spin-unpolarized to a spin-polarized state. Indeed, when we quantitatively compare the expected field dependence of the spin gap with our data we find a remarkable agreement (dashed line in Fig. 3a).

This interpretation is also supported by the transport gaps measured at $\nu = 2/3$ which have the same linear behavior, reduced by a constant due to disorder as seen in Fig. 3b. All other transport gaps are also systematically lower than the phonon excitation gaps due to disorder effects and because temperature can also couple to spin flip excitations.

The fact that we observe spin-related excitation gaps with phonons indicates that the $\nu = 2/3$ state can not be described with independent spin and Landau level indexes. This supposition is also supported by recent theoretical [18] and experimental [19] evidence suggesting that $\nu = 2/3$ state is not fully polarized, even in high magnetic fields. As a result, we may speculate that the complexity of the $2/3$ state is responsible for the appearance of a spin-forbidden transition in the phonon absorption.

In conclusion, we have measured phonon excitation gaps in the FQH regime for filling factors $\nu = 1/3, 2/5, 4/7, 3/5, 2/3, 4/3,$ and $5/3$ for eight different electron densities. For all filling factors besides $\nu = 2/3$ the measured gaps can be well described in the framework of Landau level transitions of CF involving no spin flip. The gaps measured at $\nu = 2/3$, however, correspond to a normally forbidden spin transition, pointing towards a complex not fully polarized ground state.
