Acute tryptophan depletion dose dependently impairs object memory in serotonin transporter knockout rats

Abstract

Rationale Acute tryptophan depletion (ATD) transiently lowers central serotonin levels and can induce depressive mood states and cognitive deficits. Previous studies have shown that ATD impairs object recognition in rats. Objectives As individual differences exist in central serotonin neurotransmission, the impact of ATD may vary accordingly. In this experiment, we investigated the hypothesis that male serotonin transporter knockout (SERT-/-), rats marked by a lower SERT function, are more vulnerable to the effects of ATD in an object recognition task than male wildtype (SERT+/+) and heterozygous (SERT+/-) rats.

Materials and methods Twelve male SERT+/+, SERT+/-, and SERT-/- rats were treated with standard dose and low-dose ATD using a gelatine-based protein-carbohydrate mixture lacking tryptophan. In the control treatment, L-tryptophan was added to the mixture. Four hours after treatment, the rats were subjected to the object recognition task. In addition, the effects of ATD on plasma amino acid concentrations were measured, and concentrations of 5-HT and 5-HIAA were measured in the frontal cortex and hippocampus of these rats.

Results Plasma TRP levels and central 5-HT and 5-HIAA levels were decreased in all genotypes after ATD, but effects were stronger in SERT-/- rats. The standard dose of ATD impaired object recognition in all genotypes. SERT and SERT+ rats were more vulnerable to low dose of ATD in the object recognition task compared to SERT+/- rats.

Conclusions These results indicate a greater sensitivity to ATD in SERT-/- and SERT+/- rats, which may be related to stronger central depletion effects in these rats.

Introduction

Memory is a multifaceted cognitive function relating to the acquisition and storage of information for shorter or longer periods of time and the subsequent retrieval of this
information. The role of the neurotransmitter serotonin (5-hydroxytryptamine, 5-HT) in learning and memory has been demonstrated in both humans and animals (Buhot 1997; Buhot et al. 2000; Meneses 1999; Riedel et al. 1999; Schmitt et al. 2000). Studies using the method of acute tryptophan depletion (ATD), which results in lower peripheral and central levels of tryptophan and 5-HT (Biggio et al. 1974; Fernstrom and Wurtman 1997; Gessa et al. 1974; Moja et al. 1989; Stancampiano et al. 1997), consistently report impaired memory in healthy volunteers (Park et al. 1994; Riedel et al. 1999; Sambeth et al. 2007; Schmitt et al. 2000) and rats (Jans et al. 2007a; Lieben et al. 2004b; Rutten et al. 2007). More specifically, ATD studies have shown impairments of long-term memory performance (Riedel et al. 2002) and reduced ability to actively recall, as well as recognize, words from a previously presented word list (Riedel et al. 1999). Whereas consolidation of new information into long-term memory appeared to be compromised by a reduction of central 5-HT activity; short-term memory functions were intact. Several studies have subsequently confirmed that 5-HT is specifically involved in long-term memory functioning (for review, see Sambeth et al. 2007; Schmitt et al. 2006). Interestingly, ATD did not affect long-term memory retrieval or recognition when the depletion was induced after learning and consolidation of a word list (Schmitt et al. 2000). Thus, these results suggest that consolidation of new information into long-term memory requires normal 5-HT functioning.

The serotonin transporter (SERT) has an important role in the re-uptake of 5-HT from the synapse, returning it to the presynaptic neuron where it can be degraded or retained for future release. In fact, the SERT has an essential role in serotonergic neurotransmission as it determines the magnitude and duration of the 5-HT signal in the synaptic cleft. We recently developed a SERT knockout (SERT−/−) rat using N-ethyl-N-nitrosurea-driven mutagenesis (Smits et al. 2004; Smits et al. 2006). This animal has a premature stop codon (TGC>TGA) introduced at position 3924 in the third exon encoding the second extracellular loop of the SERT protein. Consistent with the absence of SERT in these rats, northern blot analysis revealed that the mutation resulted in nonsense-mediated decay of the mutant SERT transcript and showed reduced SERT mRNA transcript in the SERT heterozygous knockout (SERT+/-) rat (Homberg et al. 2007a). In addition, [3H]citalopram (SSRI) binding to brain slices of SERT−/− rats is completely absent, whereas in SERT+/− rats, citalopram binding was reduced by approximately 40%. Moreover, extracellular 5-HT levels in the hippocampus of SERT−/− are nine-fold elevated (Homberg et al. 2007a; Olivier et al. 2008), whereas in SERT+/− rats, extracellular 5-HT levels are similar to wildtype littermates (SERT+++) (Olivier et al. unpublished data). However, intracellular 5-HT levels were reduced by approximately 75–50% in SERT−/− rats and by 45–55% in SERT+/− rats in several brain areas (Homberg et al. 2007a).

In humans, a polymorphism in the 5-HT transporter gene-linked promoter region (5-HTTLPR) results in individual differences in SERT expression and function (Heils et al. 1996; Lesch et al. 1996). Several studies have shown that 5-HTTLPR genotype can influence behavioral responses to ATD (Marsh et al. 2006; Neumeister et al. 2006; Roiser et al. 2006; Walderhaug et al. 2007). As wildtype (SERT++), heterozygous (SERT+/-), and knockout (SERT−/−) rats exhibit large differences in central 5-HT neurotransmission, the impact of ATD may vary accordingly in these rats. In this study, these different types of rats were subjected to two different doses of ATD—a standard dose and a low dose—and tested for memory in the object recognition task. Animals with lower SERT function were hypothesized to be more vulnerable to the effects of ATD on object recognition memory as they rely more heavily on 5-HT synthesis than animals in which the re-uptake mechanism is fully functional. The magnitude of the depletion was determined by measuring plasma amino acid concentrations of TRP and five other large neutral amino acids (LNAAs: valine, leucine, isoleucine, phenylalanine, tyrosine) that compete with TRP for transport across the blood–brain barrier. The ratio of TRP and these other LNAAs (TRP/ΣLNAAs ratio) is thought to be a more sensitive index of brain tryptophan availability than plasma TRP (Fernstrom 1981; Wurtman et al. 1980) because this ratio determines the amount of tryptophan that can enter the brain. Moreover, 5-HT and 5-HIAA concentrations were measured in the frontal cortex and the hippocampus brain regions involved in cognition and memory (Dalley et al. 2004; Heidbreder and Groenewegen 2003; Squire and Zola-Morgan 1991; Wurtman et al. 1980).

**Experimental procedures**

**Animals**

The serotonin transporter knockout rat (Scl6a4^Hudr) has been generated, bred, and reared in the Central Animal Laboratory of the Radboud University of Nijmegen. Experimental animals were derived from crossing SERT−/− rats that were outcrossed for four or five generations. Twelve male SERT+++, SERT+/-, and SERT−/− littermates (age: 3 to 5 months old) were used in this experiment. After weaning at the age of 21 days, ear cuts were taken for genotyping. Genotyping was performed at the Hubrecht Institute (Utrecht, The Netherlands), and the procedure has been described elsewhere (Homberg et al. 2007a). During the experiment, all animals were individually housed in standard Macrolon® type 3 cages (42×26×20 cm) in temperature-controlled
rooms (21±1°C) with standard 12/12-h day/night cycle (lights on at 7.00 a.m.) and food (Sniff, long cut pellet, Bio Services, Uden, The Netherlands) and water available ad libitum.

Drugs and chemicals

The gelatin hydrolysate (Solugel P®) was obtained from PB Gelatins (Tessenderlo, Belgium). Glucodry 210 was obtained from Tate & Lyle (Koog aan de Zaan, The Netherlands). Kaliumchloride (KCl) and calciumchloride-dihydrate (CaCl2·2H2O) were purchased from Merck (Darmstadt, Germany). L-Tryptophan was obtained from Sigma (Zwijndrecht, The Netherlands).

Treatment

During a period of 2 weeks preceding the experiment, the rats were handled and habituated to oral injections with normal tap water (up to 10 ml/kg). The experiment consisted of blood sample collection (right after the handling period), object recognition task, and brain sample collection (1 week after object recognition task). On blood and brain sampling days, rats were treated with a protein-carbohydrate mixture containing L-TRP (TRP+ group, 0.30% TRP of the total protein) or lacking L-TRP (TRP- 100 g group). In all treatment conditions, rats received two oral injections of 10 ml/kg with a 90-min interval. Blood samples were taken at baseline (10 min before the first injection) and 4 h after the first injection. Brain samples were taken without treatment and 4 h after the first treatment. The composition of the nutritional mixture is shown in Table 1. In the object recognition task, rats were tested without treatment, with TRP+, with TRP− 100 g (standard-dose ATD), and with TRP− 40 g (low-dose ATD), respectively, with a 2-day interval. The TRP− 40 g condition is a mixture containing 40 g instead of the standard 100 g of Solugel P protein per 100 ml. Because TRP was absent and amino acids were given in a lower concentration, this resulted into milder tryptophan depletion. On each testing day, behavioral testing was conducted 4 h after the first oral administration. Treatment always took place between 8.30 and 12.00 h, and the object recognition task was performed between 12.30 and 17.00 h. The rats were fasted from 14 h prior to treatment until the testing period was completed. This was done to minimize the availability of TRP from food. At the end of each testing day, the animals had ad libitum access to food.

Biochemistry

Plasma amino acid levels For the determination of plasma amino acid levels, blood samples were taken at baseline (T0; i.e., 10 min before the first oral administration) and repeated 4 h after the first administration (T4). Blood sampling was done via a tail-incision method (Fluttert et al. 2000). Promptly after collection of blood in a sodium heparin tube (Microvette® CB 300, Sarstedt, Germany), the samples were kept on ice. After centrifugation of the blood samples (at 4°C for 15 min at 3,000xg), plasma samples were stored at −70°C. Plasma amino acid concentrations were determined with a fully automated high-performance liquid chromatography (HPLC). The concentrations of the total plasma amino acids are expressed as micromoles per liter.

Brain 5-HT and 5-HIAA levels Animals were decapitated, and tissue samples (frontal cortex and hippocampus) were dissected from the brain, weighed, and stored at −80°C until further use. The tissue samples were homogenized in 250 μl of an ice-cold solution containing 5 μM clorgyline, 5 μg/ml glutathione, and 0.6 μM Nω-methylserotonin (internal standard) using a potter tube. To 100 μl homogenate, 25 μl of 2 M HClO4 was added and mixed. Then, 20 μl of 2.5 M potassium acetate was added and again mixed. After 15 min in ice water, the homogenates were centrifuged for 15 min at 15,000xg (4°C). The supernatants were diluted ten times with water before HPLC analysis. The concentration of 5-HT and 5-HIAA in the tissue

extracts were measured by HPLC with ECD. The HPLC system consisted of a pump model P100, an autosampler model AS300 (both from Thermo Separation Products, Waltham, MA, USA), an ERC-3113 degasser (Erma CR. Inc. Tokyo, Japan), an ESA Coulomb II detector with 5011 analytical cell set at potential +450 mV (ESA Inc. Bedford MA, USA), a BD 41 chart recorder (Kipp & zin, The Netherlands), and a column (150 mm × 4.6 mm i.d.) packed with Hypersil BDS C18, 5-μm particle size (Alltech Associates, USA). The mobile phase solution consisted of 50 mM citric acid, 50 mM phosphoric acid, 0.1 mM EDTA, 45 μl/l dibutylamine, and 77 mg/l 1-octanesulfonic acid sodium salt, 10% methanol; the pH of the buffer was adjusted to 3.4 with NaOH. Separation was performed at room temperature using a flow rate of 0.7 ml/min. The concentration of each compound was calculated by comparison with both the internal and the external standards. The limit of detection (signal/noise ratio 3:1) was 0.3 nM. Concentrations are expressed as nanomoles per gram. The 5-HIAA/5-HT turnover was calculated, which can be used as an index of 5-HT system activity.

Behavior

Object recognition task The object recognition task was performed as described elsewhere (Ennaceur and Delacour 1988; Prickaerts et al. 2002). The apparatus consisted of a square arena (100 × 100 × 40 cm), with an open top, dark walls, and a dark floor. Testing was carried out in dimmed white light. We used four different sets of objects that could not be displaced by the rat. Each object was available in triplicate. The different objects were (1) a bowl with handle made of green china (maximum diameter of 15 cm and a height of 9 cm); (2) a cubic box (12 × 12 × 7 cm) made of polyvinyl, with a pink topping; (3) a china trapezium cylinder (maximum diameter of 12 cm and minimum diameter of 10.5 cm) with a dish on top (diameter, 12 cm); and (4) a brown tinned cylinder (diameter, 9.5 cm and height, 15 cm).

One day preceding testing, the animals were adapted to the procedure, i.e., they were allowed to explore the apparatus (without any objects) for 3 min. In the following days, the rats were tested twice. A testing session is comprised of two 3-min trials, with a 1-h interval between trials. Two objects were placed in a symmetrical position about 10 cm away from the black wall. A rat was always placed in the apparatus facing one corner, which was the same for all rats. During the first trial, the apparatus contained two identical objects. After the first exploration period, the rat was put back in its home cage. One hour later, the rat was put back in the apparatus for the second trial but now with dissimilar objects: a familiar one and a new one. The duration of exploring each object in both trials was recorded manually on a personal computer. Exploration was defined as directing the nose to the object at a distance of no more than 2 cm and/or touching the object with the nose. Sitting on the object was not considered as exploratory behavior. In order to avoid the presence of olfactory trails, the objects were thoroughly cleaned between trials with a 70% ethanol solution. Moreover, each object was available in triplicate so that none of the two objects from the first trial had to be used as the familiar object in the second trial. In addition, all combinations and locations of objects were used in a balanced manner to reduce potential biases due to preferences for particular locations or objects.

The basic measures in the object recognition task were the times spent by rats exploring an object during trial 1 and trial 2. The discrimination index d2 [(exploration new object during trial 2 − exploration familiar object during trial 2)/total exploration time during trial 2] was calculated for each treatment condition (see Rutten et al. 2007). The d2 is a relative index of discrimination between new and familiar objects because it corrects for total exploration time in trial 2 (see Śiök et al. 2003). Rats that explored less than 5 s in any of the trials or explored only one of the objects were removed from analysis to avoid possible erroneous conclusions (see Śiök et al. 2003).

Statistical analysis

For all variables, treatment effects were analyzed using parametric statistics (ANOVA). Plasma amino acid concentrations were analyzed with repeated measures ANOVA, with factors genotype, treatment, and time. Brain 5-HT, 5-HIAA, and 5-HIAA/5-HT turnovers were analyzed with two-way ANOVA, with factors treatment and genotype. Where appropriate, post hoc testing with Bonferroni correction was used. In the object recognition task, effects of treatment and genotype on exploration times in each trial was analyzed using a two-way ANOVA. Where appropriate, post hoc testing with Bonferroni correction was used. We compared the d2 values of untreated and treatment conditions with d2 values of a virtual control group (see Śiök et al. 2003). The virtual control group had a d2 of zero, meaning that there was no object recognition. The number of animals and SEM were similar to those of our treatment groups. Comparison with this virtual control group is used to evaluate more reliably whether discrimination performance differs from zero in a certain treatment condition. The d2 values were compared with ANOVA, and a one-sided Dunnett post hoc test was used to test whether d2 in a treatment condition was higher than in the virtual control group, which would indicate that the rats are able to discriminate the objects.
**Results**

**Plasma amino acid concentrations**

To determine the effects of the treatment conditions, plasma amino acid concentrations were measured, and the TRP/ΣLNAA ratio was calculated for each measurement, treatment, and genotype (Fig. 1). Plasma TRP levels and the plasma TRP/ΣLNAA ratio decreased over the 4 h [Time: TRP: $F(1, 29)=45.20, p<0.001$; ratio: $F(1, 29)=31.43, p<0.001$]. Plasma TRP levels and the TRP/ΣLNAA ratio were lower in the TRP− 100 g group compared to the TRP+ group [Treatment: TRP: $F(1, 29)=77.46, p<0.001$; ratio: $F(1, 29)=84.91, p<0.001$]. There was no Time × Genotype × Treatment interaction effect and no Genotype × Treatment interaction effect on TRP or on the ratio (F’s< 2.15, ns). A Time × Treatment interaction effect was found on TRP [$F(1, 456.17, p=0.001$) and on the TRP/ΣLNAA ratio [$F(1, 29)=181.17, p<0.001$]. Further analysis showed that in the TRP+ condition, there was a significant increase of TRP and the TRP/ELNAA ratio over the 4 h [TRP: $F(1, 13)=26.26, p<0.001$; ratio: $F(1, 13)=23.01, p<0.001$], whereas in the TRP− 100 g condition, these were significantly decreased [TRP: $(1,14)=223.26, p<0.001$; ratio: $F(1, 14)=222.13, p<0.001$]. There was no Time × Genotype effect and no effect of genotype on TRP levels and on the TRP/ΣLNAA ratio. Thus, TRP−100 g ATD resulted in strong depletion of plasma TRP and the TRP/ΣLNAA ratio, whereas TRP+ treatment caused an increase in TRP and the TRP/ΣLNAA ratio. These effects were similar in all genotypes.

**Brain 5-HT and 5-HIAA concentrations**

To determine the central effects of the treatment, concentrations of 5-HT and 5-HIAA were determined in the frontal cortex and in the hippocampus, and for both structures, the turnover (5-HIAA/5-HT) was calculated (Table 2).

**5-HT** In the frontal cortex, a treatment effect on 5-HT was found [$F(2, 66)=41.46, p<0.001$]. Post hoc testing revealed that 5-HT levels were lower in the TRP− 100 g condition than in the untreated condition and the TRP+ condition (Fig. 2a). Furthermore, 5-HT concentrations in the TRP+ condition were higher than in the untreated rats. Moreover, a genotype effect on 5-HT in the frontal cortex [$F(2, 66)=73.76, p<0.001$] was found. Post hoc analysis showed that 5-HT levels in SERT+/− rats were lower than in SERT+/* and SERT+/* rats. No Treatment × Genotype interaction effect on 5-HT was found in the frontal cortex. In the hippocampus, similar effects were found to the prefrontal cortex. In this structure also, a treatment effect on 5-HT [$F(2, 66)=17.85, p<0.001$] was found, with lower 5-HT levels in the TRP− 100 g condition than in the untreated condition and in the TRP+ condition (Fig. 2a). Similar to the frontal cortex, 5-HT concentrations in the hippocampus were higher in the TRP+ condition than in the untreated rats. Also, a genotype effect on 5-HT was found in the hippocampus [$F(2, 66)=67.25, p<0.001$], with lower 5-HT levels in SERT−/− rats compared with SERT+/− and SERT+/* rats. No Treatment × Genotype interaction effects were found on 5-HT in the hippocampus.

In order to test our specific hypotheses, we also analyzed the effects of treatment on behavior in each experimental group separately. In the frontal cortex, 5-HT levels in the TRP− 100 g group were significantly lower than in the TRP+ group in all genotypes [Treatment: SERT+/+: $F(2, 20)=9.80, p<0.001$; SERT−/: $F(2, 21)=12.75, p<0.001$; SERT−/−: $F(2, 21)=27.88, p<0.001$]. In SERT+/− and SERT−/− rats, 5-HT levels were higher in the TRP+ group than in the untreated rats, which was not the case in SERT−/− rats. In SERT−/− rats, 5-
HT was lower in the TRP- 100 g condition than in untreated rats, which was not the case in SERT+/+ and SERT-/- rats. In the hippocampus, there was a treatment effect on 5-HT in SERT+/+ [F(2, 21)=9.29, p<0.001] and in SERT-/- rats [F(2, 21)=20.88, p<0.001] but not in SERT+/+ rats. In SERT+/+ rats, 5-HT levels in the TRP+ condition were higher than in untreated and TRP- 100 g treated rats. In SERT-/- rats, 5-HT levels in the TRP+ condition were lower than in untreated rats and TRP- 100 g treated rats. In SERT+/+ rats, 5-HT levels in the TRP- 100 g condition were lower than in the TRP+ condition and in untreated rats. No Treatment x Genotype interaction effects on 5-HIAA levels were found in the hippocampus.

In all genotypes, there was a treatment effect on 5-HIAA in the frontal cortex [SERT+/+: F(2, 20)=18.69, p<0.001; SERT-/-: F(2, 21)=4.29, p<0.05; SERT+/+: F(2, 21)=10.66, p<0.001]. Post hoc testing revealed that in SERT+/+ rats, 5-HIAA was lower in the TRP- 100 g group compared to the TRP+ group (p<0.01) and the untreated group (p<0.001). In SERT+/+ and SERT-/- rats, 5-HIAA levels were lower in TRP- 100 g compared to untreated rats (SERT+/+: p<0.05; SERT-/-: p<0.001). For the hippocampus also, there was a treatment effect in all genotypes in the hippocampus as well [SERT+/+: F(2, 20)=28.19, p<0.001; SERT-/-: F(2, 21)=7.16, p<0.001; SERT+/+: F(2, 21)=11.91, p<0.001]. Post hoc testing showed lower 5-HIAA levels in SERT+/+ and SERT-/- rats in the TRP- 100 g group compared with the TRP+ (SERT+/+: p<0.001; SERT+/+: p<0.05) and untreated group (SERT+/+: p<0.01; SERT-/-: p<0.05). In SERT-/- rats, 5-HIAA was higher in the untreated rats compared with TRP+ (p<0.05) and TRP- 100 g (p<0.001) treated rats.

5-HIAA/5-HT As seen in Fig. 2c, there was a Treatment x Genotype interaction effect on the 5-HIAA/5-HT turnover in the frontal cortex [F(4, 62)=9.628, p<0.001] caused by the high 5-HIAA/5-HT turnover rate of SERT+/+ rats. A treatment effect was found on the turnover in the frontal cortex [F(2, 62)=11.60, p<0.001]. Post hoc testing revealed that the turnover was lower in the TRP+ condition.
Fig. 2 Effect of treatment with TRP+ or TRP− 100 g on basal brain 5-HT (a), 5-HIAA (b), and 5-HIAA/5-HT turnover (c) levels in the frontal cortex and hippocampus. Bars represent mean and standard error. Numbers above the bars represent percentage difference from the untreated condition.

than in the untreated rats and in the TRP− 100 g condition. Moreover, a genotype effect on 5-HIAA in the frontal cortex [F(2, 62)=13.64, p<0.001] was found. The turnover was higher in SERT−/− rats than in SERT+/− and SERT++/++ rats. Similarly to the frontal cortex, a Treatment × Genotype interaction effect on the 5-HIAA/5-HT turnover was also found in the hippocampus [F(4, 62)=12.60, p<0.001]. This effect seems to be the result of the high 5-HIAA/5-HT turnover rate in SERT−/− rats. Moreover, a treatment effect on the turnover was found in the hippocampus [F(2, 62)= 9.02, p<0.001], again, with a lower turnover in the TRP− condition compared with the untreated rats and the TRP− 100 g condition. Similar to the frontal cortex, a genotype effect on 5-HIAA/5-HT was found in the hippocampus [F(2, 62)=28.62, p<0.001], with a higher turnover in SERT−/− rats compared with SERT+/− and SERT++/++ rats.

In all genotypes, there was a treatment effect on 5-HIAA/5-HT turnover in the frontal cortex [SERT++/++: F(2, 20)=4.64, p<0.05; SERT−/−: F(2, 21)=3.78, p<0.05; SERT+/−: F(2, 21)=16.37, p<0.001]. Post hoc testing showed that in SERT++/++ rats, the 5-HIAA/5-HT was lower in the TRP− 100 g group compared to the untreated group (p<0.05). In SERT−/− rats, 5-HIAA/5-HT was lower in TRP+ rats than in untreated rats (p<0.05). In SERT+/− rats, 5-HIAA/5-HT was higher in TRP− 100 g compared to untreated rats (p<0.001) and TRP+ rats (p<0.001). In all genotypes, there was a treatment effect in the hippocampus [SERT++/++: F(2, 20)=7.31, p<0.01; SERT−/−: F(2, 21)=4.10, p<0.05; SERT+/−: F(2, 21)=15.12, p<0.001]. Post hoc testing showed that in SERT++/++ rats, 5-HIAA/5-HT was lower in the TRP− 100 g group compared to the untreated group (p<0.01). In SERT−/− rats, 5-HIAA/5-HT was higher in the TRP− 100 g treated
rats compared to untreated rats (p<0.01) and TRP+ treated rats (p<0.001). In SERT+/− rats, no differences in 5-HIAA/5-HT were found.

Object recognition task

In order to test whether animals with lower SERT function are more vulnerable to the effects of ATD, we tested SERT+/+, SERT+/− and SERT−/− rats on object recognition memory. Exploration times of untreated rats and rats treated with TRP+, TRP− 100 g, and TRP− 40 g treated were compared (data not shown). There were no Genotype × Treatment interaction effects on exploration time in trial 1 or in trial 2. There was no effect of Genotype or Treatment on exploration time in trial 1. In trial 2, there was an effect of Genotype [F(2, 136)=3.27, p<0.05] and Treatment [F(3, 136)=3.98, p<0.01] on exploration time. Post hoc testing showed that in trial 2, exploration time was lower in the TRP− 100 g and TRP+ condition compared to the TRP− 40 g condition (p<0.05). As mentioned before, d2 values of the untreated rats and the rats treated with TRP+, TRP− 100 g, and TRP− 40 g of the present study were compared with d2 values of a virtual control group with no object recognition (see Šik et al. 2003). The effects of Genotype and Treatment on discrimination index d2 in the object recognition task are shown in Fig. 3.

There was no Genotype × Treatment interaction effect [F (8, 138)=1.28, ns] and no effect of Genotype on discrimination index d2 [F(2, 138)=2.31, ns]. A treatment effect was found on the discrimination index d2 [F(4, 146)=21.65, p<0.001]; post hoc analysis showed that the untreated d2 and the d2 in the TRP+ and TRP− 40 g condition differed from the virtual control group with no object recognition. Only in the TRP− conditions that rats were unable to discriminate between the new and familiar object after a 1-hour interval. To evaluate whether SERT+/− rats were more vulnerable to ATD treatment than SERT++ rats, treatment effects were analyzed within each genotype group. There was a treatment effect on d2 in all genotypes [SERT+/+ F(4, 50)=17.61, p<0.001; SERT+/− F(4, 43)=6.00, p<0.01; SERT−/− F(4, 45)=4.92, p<0.01]. In the SERT+/+, untreated rats and rats treated with TRP− and TRP− 40 g were different from the virtual controls but TRP− 100 g was not. In the SERT−/−, only untreated rats and TRP+ treated rats were different from the virtual controls but rats treated with TRP− 100 g and TRP− 40 g were not. In the SERT−/− rats, only the untreated rats were different from the virtual controls whereas rats treated with TRP+, TRP− 100 g, and TRP− 40 g were not.

Discussion

In the present study, the effects of standard-dose (TRP− 100 g) and low-dose (TRP− 40 g) ATD were examined in SERT+/+, SERT+/−, and SERT−/− rats in the object recognition task. The biochemical data showed plasma TRP depletion of 65% in SERT+/+, 61% in SERT+/−, and 55% in SERT−/− rats 4 h after standard-dose TRP−. This decrease in plasma TRP levels is in agreement with other ATD studies (Jans et al. 2007a; Lieben et al. 2004b). SERT+/− rats showed stronger depletion of 5-HT in the frontal cortex (63%) than SERT+/+ and SERT+/− (both 19%) rats. Similar results were found in the hippocampus, where SERT−/− rats also showed a stronger depletion (70%) compared to SERT+/− rats (18%) and SERT+/− rats (13%). Rats treated with standard-dose TRP− showed lower 5-HT levels in both brain structures compared to TRP+ treated rats and

untreated rats. These effects were most pronounced in SERT+/− rats, as only these rats showed significantly lower 5-HT in the standard-dose TRP− condition than in the untreated condition. In both the frontal cortex and hippocampus, standard-dose ATD decreased 5-HIAA to a similar extent in all genotypes. In SERT+/+ and SERT+/− rats, 5-HIAA/5-HT turnover was a bit lower in rats treated with TRP+/+ and standard-dose TRP− compared with the untreated condition, but in SERT+/− rats, this turnover ratio was much higher in the standard-dose TRP− group than in the TRP+/+ group and the untreated group. In previous studies, SERT+/− animals exhibited an increased 5-HT turnover at basal levels in the cortex and caudate putamen, but not in the amygdala medial prefrontal cortex, and orbitofrontal cortex (Homberg et al. 2007a; Jans et al. unpublished data). In line with this, untreated SERT+/− animals in this study did not have increased 5-HIAA/5-HT turnover in the frontal cortex. Although the central effects of ATD were stronger in SERT+/− rats, plasma TRP and TRP/ΣLNAA levels decreased to a similar extent in all genotypes. Thus, different effects seen in SERT+/+, SERT+/−, and SERT+/− rats after ATD were found only in the brain and not in the periphery. Previous ATD studies reported a similar dissociation between peripheral and central effects (Jans et al. 2007a; Jans et al. unpublished data). Although the reason for this difference is not known, it is interesting to note that 5-HT synthesis in brain and peripheral tissues functions differently. For example, tryptophan hydroxylase (TPH), the rate-limiting enzyme to form 5-hydroxytryptophan (5-HTP) from tryptophan, is controlled by a different isoform in the brain than in the periphery (for review, see Walther and Bader 2003). This difference in 5-HT synthesis might play a role in the different effects seen after ATD in brain and periphery.

The standard ATD dose (TRP− 100 g) is known to impair object recognition in Wistar rats (Jans et al. 2007a; Lieben et al. 2004b) and was thus expected to impair object recognition in all genotypes. The re-uptake mechanism in SERT+/− rats is fully functional, whereas this mechanism is partly functional in SERT+/+ rats and not functional in SERT+/− rats. Therefore, SERT+/− and SERT+/− rats rely more heavily on 5-HT synthesis than SERT+/+ rats. Consequently, it was hypothesized that differences in object recognition between the genotypes would occur only after the low-dose ATD treatment. It was found that all genotypes showed impaired object recognition after standard-dose ATD. The relatively mild depletion of the TRP− 40 g treatment impaired object recognition in SERT+/− and especially in SERT+/− rats but not in SERT+/+ rats, suggesting that SERT+/− and SERT+/− rats are more sensitive to the memory-imparing effects of low-dose ATD. In SERT+/+ rats, the d2 in the TRP− 40 g condition was lower than in the untreated condition but still different from the virtual control group with impaired object recognition. The stronger effects of the TRP− 40 g treatment in SERT+/− rats may be related to the stronger effects of TRP− treatment on central 5-HT levels. The same dose of TRP− 100 g had a stronger effect on central 5-HT levels in SERT+/− rats compared to SERT+/+ and SERT+/+ rats. Notably, SERT+/− rats showed impaired object recognition after TRP+ treatment as well, although their untreated d2 indicated normal object recognition when untreated. This may be related to stress associated with the ATD procedure, such as the repeated oral injections. Chronic stress is known to impair object memory (Beck and Luine 1999), and there is some evidence to suggest that diminished SERT function is associated with increased stress responsivity in humans (for review, see Canli and Lieben et al. 2007). In this way, the injection stress may have resulted in mildly impaired object recognition memory in TRP+ treated SERT+/− rats.

Several 5-HT receptors are known to be involved in memory (for review, see Buhot 1997; Perez-Garcia and Meneses 2008). ATD can modify 5-HT receptors, for example, ATD in rats reduced 5-HT1A binding in the dorsal raphe but not in the cortex and hippocampus (Cahir et al. 2007). This decrease in autoreceptor binding may represent a compensatory intrinsic homeostatic response, attempting to counteract ATD-induced decreases in central 5-HT (Cahir et al. 2007). It is interesting to note that in SERT+/− rats, the 5-HT1A receptors are less sensitive due to the nine-fold increased extracellular 5-HT levels (Olivier et al. unpublished data). The stronger ATD effects on memory in SERT+/− rats might be a result of adaptations in 5-HT receptors.

ATD has been reported to impair cognitive performance in humans (Park et al. 1994; Riedel et al. 1999, 2002; Sambeth et al. 2007; Schmitt et al. 2000), and impaired object recognition has been found in Wistar rats (Lieben et al. 2004a, b; Jans et al. 2007a). The effects of low-dose ATD on memory in groups that differ in serotonergic functioning have not been studied extensively. Booij et al. (2005) found that ATD had a dose-dependent effect on selective attention (Stroop color–word interference) in remitted depressed patients, but no other cognitive effects of low-dose ATD were observed. The magnitude of the reduction of plasma tryptophan concentrations following ATD depends on the amount and composition of the amino acid mixture (Young et al. 1989). In human studies, it has been suggested that a threshold exists that needs to be exceeded before any behavioral effects occurs since studies in which the plasma tryptophan reduction was lower than 70% generally do not find any symptomatic effects (Van Der Does 2001). A similar threshold may also exist in the rat, although the level of the threshold is likely to be lower as rat studies in general show lower plasma TRP depletion.
than human studies. In the present study, SERT\textsuperscript{−/−}, and to a smaller extent SERT\textsuperscript{+/−} rats, showed impairment in recognition memory after low-dose ATD. Thus, it may be possible that in SERT\textsuperscript{−/−}, and to a smaller extent in SERT\textsuperscript{+/−} rats, the threshold is lower in than SERT\textsuperscript{+/−} rats, and less depletion of TRP is required to cause impaired memory.

The results of this study indicate higher serotonergic vulnerability in SERT\textsuperscript{−/−} and to a lesser extent SERT\textsuperscript{+/−} rats than in SERT\textsuperscript{+/−} rats as low-dose ATD only affected memory in subjects that already have a disturbed 5-HT system. Serotonergic vulnerability means that minor changes in serotonergic functioning do not cause symptoms but make the system more vulnerable so that additional challenges of the serotonergic system may result in the occurrence of psychiatric symptoms (Jans et al. 2007b). Thus, serotonergic vulnerability can be demonstrated by challenging the 5-HT system, as is done with ATD; only vulnerable subjects will react to such manipulations with changes in behavior. Challenging the 5-HT system in vulnerable subjects can have stronger effects on the memory function of these subjects. ATD in SERT\textsuperscript{−/−} rats may therefore be a good tool to investigate serotonergic vulnerability.

Some possible limitations of this study have to be mentioned. First, plasma amino acid concentrations and brain 5-HT and 5-HIAA levels after the low-dose TRP–40 g treatment could not be determined in this study due to the limited number of rats that were available for this study. Previous standard-dose ATD studies have shown a robust reduction in plasma TRP (about 70%) and central tissue 5-HT (about 40–45%) concentrations in male Wistar rats (Lieben et al. 2004a). Lowering the concentration of Solugel protein in the TRP− mixture had dose-dependent effects on the plasma TRP\textsuperscript{+/−}/ELNAA ratio in previous research, and there was a positive correlation between the plasma TRP\textsuperscript{+/−}/ELNAA ratio and performance in the object recognition task (Lieben et al. unpublished data). We can therefore assume that the low-dose TRP− 40 g treatment resulted in milder TRP and 5-HT depletion. Further research may elucidate the exact level of peripheral and central depletion that is required to impair object recognition memory in SERT\textsuperscript{+/+}, SERT\textsuperscript{+/−}, and SERT\textsuperscript{−/−} rats. Secondly, the TRP+ treatment resulted in increased levels of plasma TRP and brain 5-HT, suggesting an active control. Essentially, this means that we compared TRP depletion and mild TRP suppletion in all rats. This may have affected behavior in the TRP+ condition. Although these treatment effects in the TRP+ condition occurred to a similar degree in all genotypes, it cannot be excluded that the mild TRP suppletion had different effects in SERT\textsuperscript{+/+}, SERT\textsuperscript{+/−}, and SERT\textsuperscript{−/−} rats. A third concern could be that the same group of rats were repeatedly subjected to ATD treatment (for the measurement of plasma levels, for the ORT, and eventually for the measurement of brain levels), although the treatment condition varied between tests. Previous ATD studies have shown that repeated treatment did not alter the effect of the treatment on the plasma TRP/ELNAA ratio and that plasma levels returned to baseline levels on the treatment day (Jans et al. unpublished data). We therefore assume that the treatment has had comparable biochemical effects throughout the study.

The aim of the present study was to investigate whether male SERT\textsuperscript{+/+}, SERT\textsuperscript{+/−}, and SERT\textsuperscript{−/−} serotonin transporter rats differed in their response to ATD with respect to object memory. Without treatment, all rats showed normal object recognition memory. After a standard 100-g dose of ATD, object recognition memory was impaired in all genotypes. However, in the low-dose ATD condition, SERT\textsuperscript{−/−} and SERT\textsuperscript{+/−} rats showed increased responsiveness to the treatment than SERT\textsuperscript{+/+} rats by showing impaired object recognition after this relatively mild ATD treatment. Therefore, ATD in SERT\textsuperscript{−/−} rats might be a valuable animal model to investigate serotonergic vulnerability. It can be concluded that there is a SERT gene–dosage effect with respect to the behavioral response to TRP depletion in the object recognition task. Because ATD decreased 5-HT levels in brain structures that play a crucial role in memory, such as the hippocampus and the frontal cortex, the outcome of the present study underlines the relevance of the serotonergic system in memory.

Acknowledgements We thank Wim Riedel, Edwin Cuppen, and Judith Homberg for cooperation and for their critical reading of the manuscript and Mark Verheul for genotyping of the rats. All experiments were carried out in accordance with institutional, national, and international guidelines for animal care and the Dutch law concerning welfare.
