(Dated: February 5, 2008)

The spin precession frequency of muons stored in the \((g - 2)\) storage ring has been analyzed for evidence of Lorentz and CPT violation. Two Lorentz and CPT violation signatures were searched for: a nonzero \(\Delta \omega_{\mu} = (\omega_{\mu}^+ - \omega_{\mu}^-)\); and a sidereal variation of \(\omega_{\mu}^+\). No significant effect is found, and the following limits on the standard-model extension parameters are obtained: \(b_2 = - (1.0 \pm 1.1) \times 10^{-25}\) GeV; \((m_\mu d_{20} + H_{XY}) = (1.8 \pm 6.0 \times 10^{-23})\) GeV; and the 95\% confidence level limits \(\Delta \omega_{\mu}^+ < 1.4 \times 10^{-24}\) GeV and \(\Delta \omega_{\mu}^- < 2.6 \times 10^{-24}\) GeV.

The minimal standard model of particle physics is Lorentz and CPT invariant. Since the standard model is expected to be the low-energy limit of a more fundamental theory such as string theory that incorporates gravity, Lorentz and CPT invariance might be broken spontaneously in the underlying theory \([1]\). At low energies, the Lorentz and CPT violation signals are expected to be small but perhaps observable in precision experiments.

To describe the effects of spontaneous breaking of Lorentz and CPT invariance, Colladay and Kostelecky\textsuperscript{2} proposed a general standard model extension that can be viewed as the low-energy limit of a Lorentz covariant theory. Lorentz and CPT violating terms are introduced into the Lagrangian as a way of modeling the effect of spontaneous symmetry breaking in the underlying fundamental theory. Other conventional properties of quantum field theory such as gauge invariance, renormalizability and energy conservation are maintained, and the effective theory can be quantized by the conventional approach. In a subsequent paper, Bluhm, Kostelecky and Lane discussed specific precision experiments with muons that could be sensitive to the CPT and Lorentz violating interactions \([3]\).

In this letter we present our analysis for CPT and Lorentz violating interactions in the anomalous spin precession frequency, \(\omega_{\mu}\), of the muon moving in a magnetic field. In experiment E821 \([4]\) at the Brookhaven National Laboratory Alternating Gradient Synchrotron, muons are stored in a magnetic storage ring that uses electrostatic quadropoles for vertical focusing. The storage ring has a highly uniform magnetic field with a central value of \(B_0 = 1.45\) T, and a central radius of \(r = 7.112\) m. Polarized muons are injected into the storage ring, and the positrons (electrons) from the parity-violating decay \(\mu^{-} \to e^{-}\nu_\mu \bar{\nu}_e\) carry average information on the muon spin direction at the time of the decay. Twenty-four electromagnetic calorimeters...
around the ring provide the arrival time and energy of the decay positrons. As the muon spin precesses relative to the momentum with the frequency $\omega_a$, which is the difference between the spin precession frequency $\omega_s$ and the momentum (cyclotron) frequency $\omega_m$, the number of high-energy positrons is modulated by $\omega_a$. In the approximation that $\vec{\beta} \cdot \vec{B} = 0$,

$$\bar{\omega}_a = \frac{q}{m} \left[ a_\mu \vec{B} - \left( a_\mu - \frac{1}{\gamma^2 - 1} \right) \vec{\beta} \times \vec{E} \right],$$

(1)

where $\gamma = 1/\sqrt{1 - \beta^2}$. The anomaly $a_\mu$ is related to the spin $g$-factor by $a_\mu = (g_\mu - 2)/2$, with the magnetic moment given by $\vec{\mu} = g(q/2m)s$, and $q = \pm e$. The ‘magic’ momentum of $p_m = 3.09$ GeV/c, ($\gamma_m = 29.3$), was used in E821 so that the second term in Eq. 1 vanishes, and the electric field does not contribute to $\omega_a$.

The magnetic field is measured using nuclear magnetic resonance (NMR) techniques [4]. The NMR frequency, averaged over both the muon distribution and the data collection period, is tied through calibration to the Larmor frequency for a free proton, and is denoted by $\omega_p$. Thus two frequencies are measured, $\omega_a$ and $\omega_p$.

In the analysis presented here, the muon frequency $\omega_a$ is obtained from a fit of the positron (electron) arrival-time spectrum $N(t)$ to the 5-parameter function

$$N(t) = N_0 e^{-\sigma t} \left( 1 + A \cos(\omega_a t + \phi) \right).$$

(2)

The normalization $N_0$, asymmetry $A$ and phase $\phi$ depend on the chosen energy threshold $E$. While more complicated fitting functions are used in the analysis for the muon anomaly [3], they represent small deviations from Eq. 2 and are not necessary for the CPT analysis. The anomalous magnetic moment $a_\mu$ is calculated from $a_\mu = R/(\lambda - R)$, where $R \equiv \omega_a/\omega_p$ and $\lambda \equiv \mu_+/\mu_p = 3.183 \times 345 \times 39(10) \times (\pm 30 \text{ ppb})$ is the muon-proton magnetic moment ratio [3].

For the muon, the Lorentz and CPT violating terms in the Lagrangian are [3]

$$L' = - a_\kappa \tilde{\psi} \gamma^\kappa \psi - b_\kappa \tilde{\psi} \gamma_5 \gamma^\kappa \psi - \frac{1}{2} H_{\kappa\lambda} \tilde{\psi} \sigma^{\kappa\lambda} \psi$$

$$+ \frac{i}{2} \epsilon_{\kappa\lambda\mu} \tilde{\psi} \gamma^\kappa \gamma^\lambda \psi + \frac{1}{2} i d_{\kappa\lambda\mu} \tilde{\psi} \gamma_5 \gamma^\kappa \gamma^\lambda \psi,$$

(3)

where $i d_{\kappa\lambda\mu} \equiv i \epsilon_{\kappa\lambda\mu} - q A_{\lambda}$, and the small parameters $a_\kappa$, $b_\kappa$, $H_{\kappa\lambda}$, $\epsilon_{\kappa\lambda\mu}$, $d_{\kappa\lambda\mu}$ represent the Lorentz and CPT violation. All terms violate Lorentz invariance with $-a_\kappa \tilde{\psi} \gamma^\kappa \psi$ and $-b_\kappa \tilde{\psi} \gamma_5 \gamma^\kappa \psi$ CPT odd; all the other terms are CPT even. In this model the conventional figure of merit $r_{g}^{m} \equiv |g_{\mu} - g_{\mu}|/g_{\text{average}}$ is zero at leading order; however effects on the anomalous spin precession frequency $\omega_a$ do exist in lowest-order [3]. The frequency $\omega_a$ is proportional to the magnetic field and therefore to $\omega_p$, so the sidereal variation of $R = \omega_a/\omega_p$ is analyzed, rather than $\omega_a$ directly.

To compare results from different experiments, it is convenient to work in the non-rotating standard celestial equatorial frame $\{\hat{X}, \hat{Y}, \hat{Z}\}$. The $\hat{Z}$ axis is along the earth’s rotational north pole, with the $\hat{X}$ and $\hat{Y}$ axes lying in the plane of the earth’s equator. The precession of the earth’s rotational axis can be ignored because its precession period is 26,000 years. In this frame the correction to the (standard model) muon anomalous precession frequency $\omega_a^{\pm}$ in Eq. 1 is calculated to be

$$\delta \omega_a^{\pm} \approx 2 b_{\pm} \cos \chi + 2 (b_1^{\pm} \cos \Omega \tau + b_0^{\pm} \sin \Omega \tau) \sin \chi;$$

(4)

$$\vec{b}_j = \pm \frac{b_j}{\gamma} + m_p d_{j0} + \frac{1}{2} \epsilon_{jKL} H_{KL}. (J=\chi, \chi, \chi),$$

(5)

where $\chi$ is the geographic colatitude ($= 90^\circ$ latitude) of the experiment location. For E821, $\chi_{BNL} = 49.1^\circ$. The sidereal angular frequency is $\Omega = 2\pi/T_s$, where $T_s \approx 23$ hours 56 minutes. Eq. 4 predicts two signatures of Lorentz and CPT violation: a difference between the time averages of $\omega_a^{\mu} = \omega_a^{\mu}$ and $\omega_a^{\mu}$, and oscillations in the values of $\omega_a^{\mu}$ at the sidereal angular frequency.

The E821 muon ($g - 2$) data have been analyzed for these two signatures. Data from the 1999 run ($\mu^+$) [7], 2000 ($\mu^+$) [8] and 2001 ($\mu^-$) [9] were used. Since bounds on clock comparisons of $^{199}$Hg and $^{133}$Cs [6, 10] place limits on the Lorentz-violating energy shifts in the proton precession frequency $\omega_p$ of $\sim 10^{-27}$ GeV, any shifts in the NMR measurements are at the mHz level, which is negligible compared to the uncertainty in the amplitude of any sidereal variation in $\omega_a$. A feedback system based on the reading from NMR probes at fixed locations around the ring keeps the field constant to within 3 ppm. Both the proton frequency $\omega_p$ and the muon frequency $\omega_a$ are measured relative to a clock stabilized to a LORAN C 10 MHz frequency standard [11], via a radio signal. The LORAN C frequency standard is based on Cesium hyperfine transitions with $m_F = 0$, which are insensitive to orientation of the clock. The Michelson-Morley type experiment of Brillet and Hall [12] establishes that the fractional frequency shift, $\Delta f/f$ of the LORAN radio signals due to the earth’s rotation is less than $10^{-14}$, so at the level of the precision of this experiment, the measured value of $\omega_p$ is independent of sidereal time. Moreover, since LORAN C is the frequency standard for $\omega_a$ as well, any sidereal variation in the LORAN C standard would cancel in $R$.

Comparison of the time averages of $\omega_a$ over many sidereal days (Eq. 4) gives $\Delta \omega_a \equiv \langle \omega_a^{\mu} \rangle - \langle \omega_a^{\mu} \rangle = (4b_{2}\gamma)/\cos \chi$. For measurements made at different $\chi$ and/or $\omega_p$,

$$\Delta R = \frac{2 b_{2} \gamma}{\cos \chi_1 + \cos \chi_2 / \omega_p}$$

$$+ 2 (m_p d_{20} + H_{XY} \left( \frac{\cos \chi_1}{\omega_p} - \frac{\cos \chi_2}{\omega_p} \right)).$$

(6)

The colatitudes for the E821 $\mu^+$ and $\mu^-$ measurements were identical, and the slightly different values of $\omega_p$ [4]
would be a variation of $R^2$ with $\omega_2 = 20$ ppm. Obtained from the CERN muon experiment, with a factor of 22 improvement over the limit that can be calculated over a set of frequencies. For a single frequency, with no corresponding periodic signal, the Lomb power is distributed exponentially with unit mean. If $M$ independent frequencies are scanned, the probability that none of them are characterized by a Lomb power greater than $z$ is $(1 - e^{-z})^M$, assuming there is no signal present. The significance (confidence) level of any peak in the data is determined by Monte Carlo simulation, using Eq. (9) to fit for $M$. The probability that this is inconsistent with the null hypothesis is negligible. The Lomb power spectrum reaches only a modest maximum of 9.93 at $f_{\text{max}}$, then 14% of the time the measured power is expected to be that large. Moreover, only a few of the Lomb power spectra taken from data subsets reveal a peak at that frequency.

In searching for a periodic signal, the Lomb power is calculated over a set of frequencies. For a single frequency, with no corresponding periodic signal, the Lomb power is distributed exponentially with unit mean. If $M$ independent frequencies are scanned, the probability that none of them are characterized by a Lomb power greater than $z$ is $(1 - e^{-z})^M$, assuming there is no signal present. The significance (confidence) level of any peak in $P_N(\omega)$ is $1 - (1 - e^{-z})^M$, which is the probability of the frequencies being scanned giving a Lomb power greater than $z$ due to a statistical fluctuation. A small value of this significance therefore indicates the presence of a significant periodic signal. In the case of equally separated points, the number of independent frequencies is almost equal to the number of time values. The lowest independent frequency, $f_0$, is the inverse of the data’s time span and the highest is roughly $(N/2)f_0$, but, because of the uneven time sampling, may be somewhat greater. More generally, the number of independent frequencies, which depends on the number and spacing of the points, as well as the number of frequencies scanned, can be determined by Monte Carlo simulation, using Eq. (9) to fit for $M$. The frequency spectrum for the 2001 data is shown in Fig. 2. The Lomb power at the sidereal frequency is 3.4. The probability that this is inconsistent with the null hypothesis is negligible. The Lomb power distribution of scanned frequencies (for $M = 3144$) shown in the lower half of Fig. 2 is consistent with an exponential distribution, indicating there is no significant time-varying signal in the data. The Lomb power spectrum reaches only a modest maximum of 9.93 at $f_{\text{max}} = 8.4 \times 10^{-5}$ Hz, and is not present in the 1999 or 2000 data sets. If there were no oscillation signal at $f_{\text{max}}$, then 14% of the time the measured power is expected to be that large. Moreover, only a few of the Lomb power spectra taken from data subsets reveal a peak at that frequency.
The significance of a possible sidereal signal in the power spectrum was carefully studied with a Monte Carlo simulation. First, a large number of artificial time spectra were generated. The distribution of times of the data points is chosen to be the same as for the real data. The value of each data point was distributed randomly with a central value equal to an average over all the actual data values, while having a standard deviation equal to that of each individual data point. The Lomb-Scargle test was then applied to 10,000 simulated data groups. The distribution of maximum Lomb power and the corresponding frequencies are shown in Fig. 3.

Next, sidereal oscillation signals of different amplitudes $A_{\Omega}$ were introduced into the simulated data, and the resulting spectra were analyzed with both the multi-parameter fit and Lomb Scargle test. Table I lists the signal amplitude required so that 95% of the simulated data sets yield a larger $A_{\Omega}$ or $P(\Omega)$ than the real data. The two analysis methods give consistent results.

Several potential systematic effects were studied. Since the sidereal period is very close to one solar day, the Lomb-Scargle test was applied to the $\omega_p$ data to check for false sidereal variations that might be produced by diurnal temperature changes. The upper limits on the amplitude of a sidereal variation in $\omega_p$ were 0.04, 0.03 and 0.08 ppm for the 1999, 2000 and 2001 data sets respectively, significantly smaller than the limit on $A_{\Omega}$ presented above. Additional studies were carried out on the 2001 data set. The data were folded back over a four sidereal day time period, (i.e. modulo four sidereal days), and then analyzed. To search for systematic effects, other sub-window time periods, where no variation was expected, were also used, e.g. 24 hours (solar day), or an arbitrary number of minutes.

No significant sidereal variation in $R$, and hence in $\omega_a$, is found in the E821 muon $(g - 2)$ data. The limits on $A_{\Omega}$ from the MPF in Table I give at the 95% confidence

TABLE I: The signal amplitude in ppm needed for 95% of the simulated data to have larger $A_{\Omega}$, or $P(\Omega)$, than that of the real data. MPF means multi-parameter fit, L-S stands for Lomb-Scargle.
level:
\[
\bar{b}_\perp^{+} = \sqrt{(\bar{b}_X^{+})^2 + (\bar{b}_Y^{+})^2} < 1.4 \times 10^{-24} \text{ GeV},
\]
\[
\bar{b}_\perp^{-} = \sqrt{(\bar{b}_X^{-})^2 + (\bar{b}_Y^{-})^2} < 2.6 \times 10^{-24} \text{ GeV}.
\]  
(11)

For the dimensionless figure of merit obtained by dividing by \(m_\mu\), we obtain \(r_\mu^{A_0} \equiv 2 \sin \chi_\mu^{A_\perp} / m_\mu < 2.0 \times 10^{-23}\) and \(r_\mu^{A_0} < 3.8 \times 10^{-23}\), which can be compared with the ratio of the muon to Planck mass, \(m_\mu / M_P = 8.7 \times 10^{-21}\). Using the E821 and CERN values of \(R\) for \(\mu^+\) and \(\mu^-\) along with Eq. (6) we find
\[
(m_\mu d_{\mu} + H_{XY}) = (1.8 \pm 6.0 \times 10^{-23}) \text{ GeV}. \quad (12)
\]

An experiment that searched for sidereal variation in transitions between muonium hyperfine energy levels \[15\], obtained \(r^{\mu} \leq 5.0 \times 10^{-22}\). Penning trap experiments with a single trapped electron obtained \(r^e \leq 1.6 \times 10^{-21}\) \[16\].

We find no significant Lorentz and CPT violation signatures in the E821 muon \((g - 2)\) data, which we interpret in the framework of the standard model extension \[3\]. Limits on the parameters are of the order \(10^{-23}\) to \(10^{-24}\) GeV, with the dimensionless figures of merit \(\sim 10^{-23}\). These results represent the best test of this model for leptons. Both \(r_\Delta^{\mu}\) and \(r_\Delta^{\mu}\) are much less than \(m_\mu / M_P\), so E821 probes Lorentz and CPT violation signatures beyond the Planck scale.

We thank the BNL management, along with the staff of the BNL AGS for the strong support they have given the muon \((g - 2)\) experiment over a many-year period. We thank A. Kostelecký for helpful comments. This work was supported in part by the U.S. Department of Energy, the U.S. National Science Foundation, the German Bundesminister für Bildung und Forschung, the Alexander von Humboldt Foundation, the Russian Ministry of Science, and the U.S.-Japan Agreement in High Energy Physics.
