Measurement of $\sigma(p\bar{p} \rightarrow Z) \cdot \text{Br}(Z \rightarrow \tau\tau)$ at $\sqrt{s} = 1.96$ TeV

We present a measurement of the cross section for $Z$ production times the branching fraction to $\tau$ leptons, $\sigma \cdot \text{Br}(Z \rightarrow \tau^+ \tau^-)$, in $pp$ collisions at $\sqrt{s} = 1.96$ TeV in the channel in which one $\tau$ decays into $e^-$ and the other into hadrons + $\nu_\tau$ or $\bar{\nu}_\tau$. The data sample corresponds to an integrated luminosity of 226 $pb^{-1}$ collected with the D0 detector at the Fermilab Tevatron collider. The final sample contains 2008 candidate events with an estimated background of 55%. From this we obtain $\sigma \cdot \text{Br}(Z \rightarrow \tau^+ \tau^-) = 237 \pm 15^{\text{(stat)}} \pm 18^{\text{(sys)}} \pm 15^{\text{(lum)}}$ pb, in agreement with the standard model prediction.

PACS numbers: 13.38.Dg, 13.85.Qk, 14.70.Hp

We present a measurement of the cross section for $Z$ production times the branching fraction to $\tau$ leptons, $\sigma \cdot \text{Br}(Z \rightarrow \tau^+ \tau^-)$, in $pp$ collisions at $\sqrt{s} = 1.96$ TeV in the channel in which one $\tau$ decays into $\mu^\pm \nu_\mu$, and the other into hadrons + $\nu_\tau$ or $\bar{\nu}_\tau$. The data sample corresponds to an integrated luminosity of 226 $pb^{-1}$ collected with the D0 detector at the Fermilab Tevatron collider. The final sample contains 2008 candidate events with an estimated background of 55%. From this we obtain $\sigma \cdot \text{Br}(Z \rightarrow \tau^+ \tau^-) = 237 \pm 15^{\text{(stat)}} \pm 18^{\text{(sys)}} \pm 15^{\text{(lum)}}$ pb, in agreement with the standard model prediction.

Measurements of the $Z$ boson production cross section times the leptonic branching fraction ($\sigma \cdot \text{Br}$) in $pp$ collisions can be used to test standard model (SM) predictions. The $\sigma \cdot \text{Br}$ to $e^+ e^-$ and $\mu^+ \mu^-$ in $pp$ collisions has been measured by the UA1 and UA2 collaborations at $\sqrt{s} = 630$ GeV [1], by the CDF collaboration at $\sqrt{s} = 1.8$ TeV and $\sqrt{s} = 1.96$ TeV [2], and by the D0 collaboration at $\sqrt{s} = 1.8$ TeV [3]. The $Z$ boson branching ratio
to $\tau^+\tau^-$ has been measured with high precision by the CERN $e^+e^-$ collider (LEP) experiments [4]. These measurements are in good agreement with SM expectations and lepton universality. We report here the first measurement of $\sigma_{BR}(Z \rightarrow \tau^+\tau^-)$ in $pp$ collisions. This measurement provides a test of the SM as a deviation from the expected value would be an indication of anomalous production of $\tau^+\tau^-$ pairs in $pp$ collisions. It also verifies that the DØ detector can identify isolated $\tau$ leptons in the energy range covered by $Z$ boson decays, which could be critical in the search for non-SM signals such as supersymmetric (SUSY) particles in certain regions of the SUSY parameter space, or heavy resonances decaying into fermion pairs with enhanced coupling to the third generation.

The DØ Run II detector is fully described in [5]; a more succinct description of details relevant to this measurement can be found in [6]. The $Z \rightarrow \tau^-\tau^+$ candidate selection strategy focused on one $\tau$ lepton decaying to muon by triggering on the single muon using a three-level triggering system. The first level used the timing and position information in the muon scintillator system to find muon candidates. The second level used digital signal processors to form segments defined in the muon drift chambers. The third level used software algorithms executed on a computer farm to reconstruct tracks in the central tracking system and required at least one track with transverse momentum $p_T > 10$ GeV. The integrated luminosity of the selected sample is 226 pb$^{-1}$ determined with a 6.5% uncertainty [7].

After full reconstruction, the events were required to have an isolated muon with $p_T^\mu > 12$ GeV and a $\tau$ candidate. The muon isolation required less than 4 GeV in the calorimeter in a cone $R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} < 0.1$ (where $\phi$ is the azimuthal angle and $\eta$ is the pseudorapidity) around the muon, less than 4 GeV in an annulus $0.1 < R < 0.4$, and fewer than three tracks (other than the muon) with $p_T > 0.25$ GeV within $R < 0.7$.

Most $\tau$ leptons decay to one or three long lived charged particles plus up to three $\pi^0$ mesons that can be observed in the detector. The $\tau$ candidates were found by constructing a calorimeter cluster made of all the towers with energy above a preset threshold around a seed tower within $R < 0.5$, keeping only clusters with $E_T > 5$ GeV and $E_T^{orr} > 4$ GeV, where $E_T$ ($E_T^{orr}$) is the transverse energy with respect to the beam axis within $R < 0.5$ ($R < 0.3$), and requiring $rms_T < 0.25$ (see Table I caption) and at least one associated track with $p_T > 1.5$ GeV within $R < 0.3$. If there was more than one track, the one with highest $p_T$ was associated with the $\tau$ candidate. A second track was added if the invariant mass calculated from the tracks was less than 1.1 GeV, and a third if the invariant mass was less than 1.7 GeV and the total charge was not $\pm 3$. Candidates with total charge zero were discarded. Finally, subclusters were constructed from the cells in the EM section of the calorimeter belonging to the $\tau$-cluster. The minimum $E_T$ required for an EM subcluster was 800 MeV. Three types of $\tau$ candidates were identified according to tracking and calorimetry information: 1) single track with no subclusters in the electromagnetic (EM) section of the calorimeter ($\tau$-like), 2) single track with EM subclusters ($\rho$-like), or 3) more than one associated track. No attempt was made to separate hadrons from electrons (which can contribute to both $\tau$-type 1 and $\tau$-type 2).

Additional requirements (which depend on the $\tau$-type) imposed on the selected events to enhance the signal-to-background ratio are shown in Table I. The background increases rapidly with decreasing $p_T^\tau$ or decreasing $E_T^\tau$. It is significantly lower for $\tau$-type 2 than for the other $\tau$-types, so a lower $E_T^\tau$ cut is warranted for that $\tau$-type. The $|\phi_{\mu} - \phi_{\tau}| > 2.5$ cut takes advantage of the fact that most Z bosons have low $p_T$ and thus the decay $\tau$ leptons are back-to-back in $\phi$. The longitudinal shape variable $R^\tau_{trk}$ (defined in Table I caption) is used to remove misidentified muons because it has a distribution that peaks at much lower values for muons than for $\tau$ leptons.

The $\tau$ leptons from a $Z$ boson decaying to hadrons + $\nu_{\tau}$ have average visible energy ($E_T^\tau$) of the order of 25 GeV and need to be separated from a very large background of jets. To further reduce the jet background, a neural network (NN) [8] consisting of a single input layer containing several nodes (one for each input variable), a single hidden layer with the same number of nodes, and a single output node was used. A separate NN was trained for each type using a Monte Carlo (MC) sample of single $\tau$ leptons uniformly distributed in $E_T$ and $\eta$ and overlaid with a minimum bias event for signal [9], and jets recoiling against non-isolated muons from data for background. The NN input variables were chosen to minimize the dependence on the $\tau$ energy and to exploit the narrow width of the energy deposition in the calorimeter, the low track multiplicity, the low $\tau$ mass, and the fact that $\tau$ leptons from $Z$ boson decays are well isolated.

$^a rms_T = \sqrt{\sum_{i=1}^{n}[(\Delta \phi)^2 + (\Delta \eta)^2]/E_T^i/E_T}$, where $i = 1, ..., n$ is the index of the calorimeter tower associated with the $\tau$-cluster; $\Delta \phi$ and $\Delta \eta$ are the $\phi$ and $\eta$ difference between the center of the $\tau$-cluster and calorimeter tower $i$.

$^b R^\tau_{trk} = (E_{T} - E_{T}^{H})/E_{T}^{H}$, where $E_{T}^{H}$ is the energy deposited in a window of $5 \times 5$ towers (each tower of size $\phi \times \eta = 0.1 \times 0.1$) around the $\tau$-track in the coarse hadronic (CH) section of calorimeter.
input variables were:

1. \( \text{profile} = (E_{T1} + E_{T2})/E_T \), where \( E_{T1} \) and \( E_{T2} \) are the \( E_T \) of the two most energetic calorimeter towers. Used for all \( \tau \)-types.

2. \( \text{caliso} = (E_T - E_{T\text{corr}})/E_{T\text{corr}} \). A calorimeter isolation parameter used for all \( \tau \)-types.

3. \( \text{trkiso} = \frac{\Sigma \rho_{lT}}{\Sigma \rho_{lT}} \), where \( \rho_{lT} \) (\( \rho_{lT} \)) is the \( p_T \) of a track within a \( R < 0.5 \) cone not associated (associated) with the \( \tau \) candidate. A track isolation parameter used for all \( \tau \)-types.

4. \( (E^{EM1} + E^{EM2})/E_T \) in a \( R < 0.5 \) cone, where \( E^{EM1} \) and \( E^{EM2} \) are the energies deposited in the first two layers of the EM calorimeter. A parameter used for \( \tau \)-type 1 to reject jets with one energetic charged track and soft \( \pi^0 \) mesons.

5. \( p_{\text{cal}}^{lT} / E_T \), where \( p_{\text{cal}}^{lT} \) is \( p_T \) of the highest \( p_T \) track associated with the \( \tau \). Used for \( \tau \)-type 1 and 3.

6. \( p_{\text{cal}}^{lT} / (E_T - \text{caliso}) \). A parameter used for \( \tau \)-type 2 that measures the correlation between track and energy deposition in isolation annulus.

7. \( \epsilon_{12} = \sqrt{\Sigma \rho_{lT}^{EM} / E_T} \), where \( E_T^{EM} \) is the transverse energy deposited in the EM layers of the calorimeter. Used for \( \tau \)-types 2 and 3.

8. \( \delta_{\alpha} = \sqrt{(\Delta \phi/ \sin \theta)^2 + (\Delta \eta)^2} \), where the differences are between \( \Sigma \tau \)-tracks and \( \Sigma \text{EM-clusters} \). In the small angle approximation the observed \( \tau \) mass is given by \( \epsilon_{12} \cdot E_T \cdot \delta_{\alpha} \). Used for \( \tau \)-types 2 and 3.

The dominant background is from multijet (QCD) processes, mainly from \( bb \) events where the muon isolation requirement is met and a jet satisfies the \( \tau \) selection criteria. The other sources of background are \( W \to \mu \nu \) + jets and \( Z/\gamma^* \to \mu^+ \mu^- \) with one of the muons misidentified as a \( \tau \) lepton. The \( R_{\tau} > 0.7 \) cut removed 70% of the \( \mu^+ \mu^- \) background while keeping 98% of the expected \( Z/\gamma^* \to \tau^+ \tau^- \) events. The number of events that did not satisfy this criterion was used to estimate the background from misidentified muons remaining in the sample after the cut.

The selected 29,021 events were separated into two samples: \( \mu \) and \( \tau \) of opposite charge sign (OS), and \( \mu \) and \( \tau \) of same charge sign (SS). The OS sample contains the signal. The SS sample is dominated by background and was used to predict the QCD background distributions in the signal sample. From detailed studies of a sample of data with non-isolated muons, we established that this procedure is sound if one accounts for a small excess of OS over SS events that varies somewhat with the \( \tau \)-type. The correction factors \( (f_i, \text{where} \ i \ \text{denotes} \ \text{the} \ \tau \text{-type}) \) were determined to be \( 1.06 \pm 0.06, 1.09 \pm 0.03 \), and \( 1.03 \pm 0.02 \), by taking the ratio of OS to SS data in the non-isolated muon sample. There was no observable dependence of \( f_i \) as function of \( E_T \), of NN output (\( NN \) ) values, or of the muon parameters. A possible dependence of \( f_i \) on the degree of isolation of muons coming from jets was checked by looking at the variation in the \( f_i \) as function of \( p_T \) relative to the jet axis and varying the muon isolation. No variation was observed within the systematic uncertainties quoted. An overall 2% systematic uncertainty was added for the extrapolation to the \( NN > 0.8 \) region. These factors do not fully account, however, for the contribution from \( W \to \mu \nu \) + jets, which have a larger excess of OS over SS and different distributions. The additional contribution of this channel to the signal sample is estimated from PYTHIA [9] MC samples. The MC is normalized using the OS and SS data with \( p_T > 20 \text{ GeV} \), \( |\eta| < 2.0 \), and \( 0.3 < NN < 0.8 \) (in this region \( W \to \mu \nu \) events dominate over the QCD background). The additional contribution to the background from \( W \to \tau \nu \) events was ignored as it is a small fraction of the uncertainty on the contribution from \( W \to \mu \nu \) events.

Figure 1 shows the \( NN \) distributions for each \( \tau \)-type (and the sum) for the signal sample, the predicted background and the result of adding the predicted signal (from \( Z/\gamma^* \to \tau \tau \) MC [9]) to the background. Table II shows the total number of events observed and predicted before and after the final cut \( NN > 0.8 \). Distributions of background subtracted data are in very good agreement with those expected from \( Z \to \tau \tau \) MC. Figure 2 compares the expected \( E_T \) and \( p_T \) (adding all \( \tau \)-types) signal distributions to the predicted background distributions, and to the distributions obtained by subtracting the predicted background from the signal sample distributions.

The total event efficiency \( \epsilon_{\text{TOT}} \) summed over \( \tau \)-types 1, 2, and 3 is 1.52% for \( M_{TT} \) greater than 60 GeV. The total efficiency accounts for all losses due to branching ratios, geometrical acceptance, reconstruction and trigger efficiencies. It is corrected for the small difference between MC and data reconstruction efficiencies. The contributions of the three \( \tau \)-types to the signal in the final data sample are 13%, 58%, and 29%.

The cross section times branching ratio for \( Z/\gamma^* \to \tau^+ \tau^- \) is given by \( N_{\text{signal}}/(\epsilon_{\text{TOT}} \cdot f \cdot L \) dt) where \( N_{\text{signal}} \) is given by the number of signal events and \( f \cdot L \) dt is the integrated luminosity of the sample studied. \( N_{\text{signal}} = 865 \pm 55 \) (statistical uncertainty only) is the number of OS events of all \( \tau \)-types after selecting the events with \( NN > 0.8 \), subtracting the estimated background (see Table II), and subtracting the number of expected events in the sample with \( M_{TT} \) less than 60 GeV (3.5%).

The systematic uncertainties on the cross section measurement are listed in Table III. The uncertainty (2.5%) due to the energy scale was estimated from the change in the acceptance when scaling the energy in MC events by the energy difference between MC and data (as de-
theoretical cross section of $257\pm9$ pb for tributions and the background-subtracted data distribu-

tions. The distributions of NN input variables are in good agreement with those predicted adding $Z/\gamma^* \rightarrow \tau^+\tau^-$ MC and the estimated background; two are shown in Fig. 3.

The QCD systematic uncertainty (3.5%) is due to the uncertainty in determining $f$. The uncertainty in the $Z/\gamma^* \rightarrow \mu^+\mu^-$ and $W \rightarrow \mu\nu$ backgrounds (2.0% and 2.3%) come from the statistical uncertainty in determining their contribution, while the $Z/\gamma^* \rightarrow \tau^+\tau^-$ MC systematic uncertainty reflects limited signal MC statistics. The $\varepsilon_{data}/\varepsilon_{MC}$ is dominated by the uncertainty in estimating the difference in $\tau$-type 3 tracking efficiency between MC and data using the the ratio of two- to three-

a Efficiency uncertainty due to uncertainty in parton distribution function (PDF).

b The QCD background is estimated by multiplying the number of SS events by $f_1$ (described in the text).

c The predicted contribution is the number of events that must be added after subtracting the corrected number of SS events from OS events.

d The predicted number of $Z/\gamma^* \rightarrow \tau^+\tau^-$ events is based on a theoretical cross section of $257\pm9$ pb for $M_{\tau\tau} > 60$ GeV [10] plus 3.5% predicted from MC for the number of events expected with $M_{\tau\tau} < 60$ GeV.

terminated by the $p_T$ imbalance in photon + jet events). The systematic uncertainty due to the NN performance (2.6%) was estimated by generating ensembles of Monte Carlo events in which the number of events in each bin of distributions of NN input variables was allowed to fluctuate by the uncertainties in the difference between MC distributions and the background-subtracted data distribu-

FIG. 2: $E_T^Z$ [(a), (c)] and $p_T^Z$ [(b),(d)] distributions after $NN > 0.8$ cut: (a), (b) estimated background (open triangles) and predicted $Z \rightarrow \tau\tau$ signal (histogram); (c), (d) background subtracted data (open circles) and predicted $Z \rightarrow \tau\tau$ signal.
FIG. 3: Distributions for OS data, background and background plus signal of two NN input variables before [(a), (b)] and after [(c), (d)] $\sqrt{s}N > 0.8$ cut: (a), (c) profile; (b), (d) caliso.

prong events between background subtracted data and $Z/\gamma^* \rightarrow \tau^+\tau^-$ MC in $\tau$-type 3 candidates. The uncertainty from differences in subcluster reconstruction, single isolated track reconstruction and muon isolation add up to about 1%.

The trigger efficiencies were estimated using $Z \rightarrow \mu^+\mu^-$ data, the systematic uncertainty comes from the statistical uncertainty in that data; the uncertainties include dependencies on $\eta$ and $\phi$. Systematic uncertainties from all other sources are less than 1%. Thus we obtain

$$\sigma \cdot Br(Z/\gamma^* \rightarrow \tau\tau) = 252 \pm 16(\text{stat}) \pm 19(\text{sys}) \text{ pb}$$

for $M_{\tau\tau}$ greater than 60 GeV. The quoted statistical uncertainty is the uncertainty from OS and SS statistics (excluding the uncertainties on the correction factors). This yields, after removing the $\gamma^*$ contribution,

$$\sigma \cdot Br(Z \rightarrow \tau\tau) = 237 \pm 15(\text{stat}) \pm 18(\text{sys}) \pm 15(\text{lum}) \text{ pb}$$
in good agreement with the NNLO standard model prediction of 242\pm9 pb [10].
