Abstract

We study polylithiated molecules as building blocks for hydrogen storage materials, using first-principles calculations. CLi4 and OLi2 bind 12 and 10 hydrogen molecules, respectively, with an average binding energy of 0.10 and 0.13 eV, leading to gravimetric densities of 37.8 and 40.3 weight % H. Bonding between Li and C or O is strongly polar and H2 molecules attach to the partially charged Li atoms without dissociating, which is favorable for (de)hydrogenation kinetics. CLiₙ and OLiₘ molecules can be chemically bonded to graphene sheets to hinder the aggregation of such molecules. In particular B or Be doped graphene strongly bind the molecules without seriously affecting the hydrogen binding energy. It still leads to a hydrogen storage capacity in the range 5-8.5 wt.% H.
Introduction

In recent years we observe a widespread effort aimed at finding alternatives to fossil fuels. The goal is to apply renewable resources that meet the increasing global demand for energy, while at the same time cut down CO\textsubscript{2} emissions.\textsuperscript{1} Hydrogen is a potential energy carrier, since it can be produced sustainably and is one of the most abundant elements.\textsuperscript{2} Burning hydrogen does not affect the environment as only water is produced. On board utilization of hydrogen on a large scale is hampered, however, by the lack of efficient hydrogen storage systems. Some of the methods suggested so far are high pressure gas tanks, low temperature liquid hydrogen tanks, chemical solid state storage such as metal-hydrides, and physisorption of hydrogen by materials with a high surface area.\textsuperscript{3} Physisorption offers the possibility of storing hydrogen in molecular form. From kinetic considerations this is advantageous over chemical storage in atomic form, which requires dissociation of the hydrogen bond and the formation of a hydride. Materials that are mainly based upon carbon are cheap, lightweight, and can have large internal surfaces. The bottleneck of physisorption by such materials lies in the weak interaction of hydrogen molecules with the host materials.\textsuperscript{4} As a result, very low temperatures or high pressures are necessary to attain meaningful storage capacities.\textsuperscript{5} One can imagine encapsulating hydrogen in carbon nanocages, but the applicability of such systems is unknown at present.\textsuperscript{6} At the moment none of the above methods have achieved all requirements of a hydrogen storage system.

Previous studies have shown that isolated metal atoms or ions can bind hydrogen molecules, where the type of bonding depends on the metallic species. Transition metal atoms bind hydrogen molecules through weak multicenter chemical bonds called Kubas bonds.\textsuperscript{7,8,9} Alkali and alkaline earth ions bind hydrogen molecules through electrostatic (charge-multipole) and polarization (charge-induced multipole) interactions.\textsuperscript{10} Of particular interest is the lightweight Li\textsuperscript{+} ion, which can bind up to six hydrogen molecules with an average binding energy of 0.19 eV/H\textsubscript{2}.\textsuperscript{11} This is close to optimal, as the binding energy should be around 0.15 eV/H\textsubscript{2} for storage of hydrogen gas at moderate pressures.\textsuperscript{12} For this type of bonding it is essential that Li is ionized. Moreover, Li atoms need to be prevented from clustering, as, for instance, steric hindrance would
result in a significant reduction of the amount of hydrogen molecules that can be bonded. Recent research therefore focuses on the hydrogen storage properties of Li-doped carbon nanostructures. A limited amount of Li can be introduced by doping without the Li atoms clustering, consequently restricting the wt.% of adsorbed hydrogen significantly.

Polylithiated molecules are species that contain a large density of Li atoms. Such molecules have been studied experimentally and theoretically for a number of years, but never with an eye on their potential for hydrogen storage. The main focus has been on the interaction of single atoms such as C or O, with multiple Li atoms. The first polylithiated molecule, OLi$_3$, has been identified by mass spectroscopy by Wu et al. and its bonding characterized quantum chemically by Schleyer et al. The latter group has also predicted the existence of the carbon based polylithiated molecules CLi$_5$ and CLi$_6$, which has later been confirmed experimentally by Kudo. These studies have stimulated extensive research into the properties of CLi$_n$ and OLi$_m$ molecules. C—Li and O—Li bonds are strongly polar, resulting in a significant positive charge on the Li atoms. This should facilitate electrostatic bonding to hydrogen molecules, as discussed above.

In this paper we study the hydrogen storage properties of the polylithiated molecules CLi$_n$, $n = 3-5$ and OLi$_m$, $m = 1-4$. We find that each Li atom can bind multiple hydrogen molecules and that the binding energy increases with the partial charge on the Li atom. In particular, a CLi$_4$ molecule binds up to 12 and an OLi$_2$ molecule up to 10 hydrogen molecules, with binding energies in the range of 0.10-0.14 and 0.13-0.21 eV/H$_2$, respectively. The corresponding gravimetric storage densities are 37.8 wt.% H for CLi$_4$H$_{24}$ and 40.3 wt.% H for OLi$_2$H$_{20}$. Such extremely high densities make polylithiated molecules fascinating building blocks for hydrogen storage materials. Aggregation of CLi$_n$ or OLi$_m$ molecules would be detrimental for the reversibility of hydrogenation. Therefore we explore the possibilities of attaching polylithiated molecules to carbon nanostructures, in particular graphene, in order to immobilize them. Using dopants such as B or Be, one can increase the binding of the molecules to the substrate, without weakening the binding of hydrogen to the molecules. This scenario leads to several interesting structures with gravimetric densities $> 5$ wt.% H.
Computational Details

The calculations are performed at the level of density functional theory (DFT), using the PW91 generalized gradient approximation (GGA), and the projector augmented wave (PAW) method, as implemented in the Vienna \textit{ab initio} simulation package (VASP). The PAW potentials treat the H 1s, Li and Be 1s, 2s, B, C and O 2s, 2p as valence electrons. With a plane wave kinetic energy cutoff of 518 eV the total energies are converged on a scale of $10^{-3}$ eV/atom. Geometries are optimized without any symmetry constraints, using the conjugate gradient (CG) algorithm. Convergence criteria of $10^{-4}$ eV and 0.02 eV/Å are applied for the energy difference between consecutive electronic steps and the total remaining forces on the atoms, respectively. Single molecules are treated within a cubic box with a cell parameter of 20 Å, using periodic boundary conditions and Γ-point sampling. In the graphene systems to be discussed below we use a 4×4 in-plane graphene supercell and a 3×3 regular k-point mesh to sample the Brillouin Zone (BZ). The final total energies and charge densities of the optimized structures are obtained using the corrected linear tetrahedron method.

Results and Discussion

Polylithiated Molecules

First we analyze the interaction of molecular hydrogen with CLi$_n$ and OLi$_m$ molecules. As the electron affinities of C and O are much larger than that of Li, the C–Li and O–Li bonds are very polar. If C and O become hypercoordinated by Li atoms, i.e. CLi$_n$ with $n \geq 5$, or OLi$_m$ with $m \geq 3$, the Li coordination shells become increasingly metallic and the average charge on the Li atoms decreases. The binding of hydrogen to these atoms is dominated by electrostatic and polarization interactions. Therefore, to maximize hydrogen binding energies, the charge on the Li atoms should be maximal and one needs to avoid hypercoordination of the C or O atoms. In CLi$_4$ or OLi$_2$ all valence electrons are involved in C–Li and O–Li bonds, respectively, maximizing the charge on
Figure 1: Optimized geometries of (a) CLi₄H₈, CLi₄H₂₄, and (b) OLi₂H₄, OLi₄H₂₀ complexes. Carbon, oxygen, lithium and hydrogen atoms are shown as black, red, yellow and blue spheres, respectively.

the Li atoms. The most stable geometries of CLi₄ and OLi₂ have a high symmetry, i.e. $T_d$ and $D_{xh}$, respectively. All Li atoms in a molecule are then equivalent.

A Bader charge analysis of the calculated self-consistent charge densities gives a charge of +0.82$e$ on each of the Li atoms in CLi₄, and a charge of +0.88$e$ on the Li atoms in OLi₂.¹¹ These high charges facilitate the electrostatic bonding of hydrogen molecules to the Li atoms in these molecules, similar to that in isolated Li⁺ ions.¹¹ Hydrogen molecules then cluster around the Li sites of the CLi₄ and OLi₂ molecules. Examples of the structures of hydrogenated molecules are shown in Figure 1 and bond lengths before and after hydrogenation are given in Table 1.

Table 1: Calculated bond lengths (Å), Bader charges ($e$), hydrogen binding energies $E_b^{H_2}$ (eV/H₂) and gravimetric hydrogen densities of CLi₄ and OLi₂ molecules. For Li—H₂ the bonding distance is measured between Li atom and the center of H—H bonds. Average numbers are given and the numbers between () indicate the spreads.

Also given in Table 1 are the hydrogen binding energies, which are calculated by subtracting the total energy of the hydrogenated polylithiated molecules from the sum of the total energies of the isolated polylithiated molecules and the hydrogen molecules, divided by the number of hydrogen molecules. Each Li atom in a ClLi4 molecule can bind three H2 molecules as shown in Figure 1, which leads to 37.8 wt.% H. The average binding energy decreases from 0.14 eV for the first H2 molecule (per Li atom), to 0.10 eV for the fully hydrogenated state. The decrease reflects a net repulsive interaction between the H2 molecules surrounding a Li atom. Steric hindrance prevents binding a fourth H2 (at least with a binding energy > 0.04 eV). The H2 binding energies are consistent with those found for isolated Li+ ions, bearing in mind that the Li atoms in ClLi4 have a somewhat reduced charge.

OlLi2 molecules bind hydrogen more strongly than ClLi4 molecules. As the net charge on a Li atom in OlLi2 is larger than in ClLi4 this can be expected if the binding is electrostatic. Because the Li atoms in OlLi2 are less crowded than in ClLi4, each Li atom can accommodate up to five H2 molecules, before steric hindrance prevents binding of additional hydrogen. The average binding energy decreases from 0.21 eV for the first H2 molecule (per Li atom) to 0.13 eV in the fully hydrogenated state. It leads to 40.3 wt.% H for the OlLi2H20 complex.

The fully hydrogenated ClLi4H24 and OlLi2H20 complexes keep a high symmetry, i.e. Td and D2d, respectively. In intermediate hydrogenation stages the symmetry can be broken, see Figure 1. After hydrogenation the C–Li and O–Li bonds are stretched by 1% respectively 4%. This is accompanied by a slight increase of the partial charge on Li by 4% respectively 0.6%. The optimized calculated bond length of an isolated H2 molecule is 0.748 Å. Table 1 shows that in the complexes the H–H bond lengths increase by 1-6%. The limited size of these changes agrees with the notion of a weak interaction with the H2 molecules. The absolute size of these changes generally correlates with the binding energy.
Adsorption on Graphene

It is clear that individual CLi₄ and OLi₂ molecules can bind a substantial number of H₂ molecules. In order to maintain reversibility during repeated hydrogen loading and unloading cycles, one should however prevent the formation of clusters or aggregates of CLi₄ or OLi₂ molecules. From a thermodynamic point of view such clusters could form. For instance, the equilibrium geometry of C₂Li₈ is shown in Figure 2(b). The energy of this structure is 2.54 eV/CLi₄ lower in energy than that of two separate CLi₄ molecules. Similarly, two OLi₂ molecules can form a cluster with a binding energy of 1.37 eV/OLi₂, see Figure 2(d). Presumably also structures of larger clusters exist that have a favorable binding energy. One could rely on kinetic barriers preventing clustering of polylithiated molecules. Here we consider alternative possibilities, which consist of immobilizing the molecules by binding them to a holder template. Microporous carbon and carbon nanostructures would be obvious substrates for these molecules.

As a prototype system we consider binding to a single sheet of graphite, i.e. to graphene. We use a 4×4 graphene supercell, which contains 32 atoms and has an optimized cell parameter of 9.866 Å. This cell is sufficiently large to prevent a direct interaction between molecules bonded to graphene in neighboring cells. The calculated binding energies of single CLi₄ and OLi₂ molecules bonded to graphene are 0.73 and 0.55 eV, respectively. Both of these energies are considerably...
smaller than the corresponding molecular dimerization energies, indicating that the interaction with the substrate is not sufficiently strong. One has to consider increasing this interaction.

For this we pursue two different strategies consisting of modifying the molecules or the substrate, respectively. Removing one Li atom from CLi₄ or OLi₂ strengthens the bonding to graphene. The calculated binding energy between CLi₃ and graphene is 2.00 eV. CLi₃ molecules on graphene are preferably positioned over the center of C—C bonds. Both faces of graphene can be functionalized, which leads to a geometry as shown in Figure 3(a). This structure is stable, but it is not the absolute minimum energy structure. C₂Li₆ in its equilibrium structure, cf. Figure 2(a),⁴⁵ has a binding energy of 3.86 eV/CLi₃ with respect to two separate CLi₃ molecules. It means that, although the CLi₃—graphene structure is kinetically stable, there is still a thermodynamic driving force towards aggregation of CLi₃ molecules.

OLi molecules also bind strongly to a graphene substrate. Since an OLi molecule is smaller than a CLi₃ molecule, it is possible to quadruple the packing density of these molecules, as is shown in Figure 3(b). OLi molecules preferentially bind to the substrate through the formation of an O—C bond. The calculated binding energy is 2.22 eV, which is comparable to the 2.26 eV/OLi aggregation energy of two OLi molecules into O₂Li₂. The O₂Li₂ molecule has a planar structure as shown in Figure 2(c). This means that the OLi-graphene structure is close to being
Adsorption on Doped Graphene

Another possible way of increasing the binding between polylithiated molecules and the substrate is by chemical modification of the graphene layer.\textsuperscript{46} Introducing an impurity in graphene might for instance not only strengthen the interaction with CLi\textsubscript{\textit{n}} and OLi\textsubscript{\textit{m}} molecules, but could also maintain the positive charge on the Li atoms, and therefore the binding to H\textsubscript{2} molecules. Here we consider modification of graphene by atomic substitution of C by B or Be atoms. Previous studies have shown that B doping of graphene does not cause any major deformation of the graphene structure.\textsuperscript{47} B doping concentrations of as high as 17 at. % can be achieved in thin films.\textsuperscript{48} From experiment it has been suggested that the preferential geometry upon high B doping has two B atoms in para positions of an hexagonal ring in the graphene plane, as shown in Figure 4(b). Indeed, the stability of this geometry has recently been confirmed by a theoretical study.\textsuperscript{49} Here we consider such a double B substitution in our 4×4 graphene supercell, which gives a doping concentration of 6.25 at. %.

As an alternative to B doping we also consider substituting C with Be atoms. Replacing one C with a Be atom does not alter the planar structure of graphene. It is energetically advantageous
however to replace a single C atom by a pair of Be atoms. The two Be atoms are then displaced above and below the graphene plane by 0.855 Å, as shown in Figure 4(a), whereas the rest of graphene maintains its original structure. The Be atoms can act as pedestals that increase the distance between the graphene plane and the molecules we are going to attach, which could limit steric hindrance. All of the Be or B doped graphene structures have a nonmagnetic ground state.

Modifying graphene by Be or B doping increases its interaction with polylithiated molecules. The molecules preferentially bind to the dopant atoms and form C,O—B,Be bonds. From the point of view of binding strength, there is no need to modify the molecules by extracting a Li atom before attaching them to the substrate. CLi₄ binds to a B or a Be site with binding energies of 2.91, 3.81 eV, respectively. The binding geometries are shown in Figure 5. The binding between OLi₂ and B or Be doped graphene has an energy of 2.49, 3.76 eV, respectively. Since all these binding energies are well above the molecular dimerization energies one expects that aggregation of these molecules is now suppressed. Remarkably, doped graphene also forms strong bonds to other CLiₙ and OLiₘ molecules, including hypercoordinated ones such as CLi₅, OLi₃ and OLi₄, leading to similar binding geometries. The binding energies are given in Table 2 and examples of binding geometries are shown in Figure 5.

With the polylithiated molecules strongly bonded to (doped) graphene we now study the hy-

hydrogenation properties of these systems. For CLi3 and OLi bonded to undoped graphene we find that each of the Li atoms in the molecules above and below the graphene plane can bind three H2 molecules, see Table 3. The average hydrogen binding energy is 0.10 and 0.12 eV, respectively, which is comparable to that in free CLi4 and OLi2 molecules, compare Table 1. The resulting geometries are given in Figure 3. The gravimetric densities in the CLi3- and OLi-graphene systems are 7.46 and 7.85 wt.% H, respectively.

As discussed above, doping of graphene with Be or B increases the binding of polylithiated molecules to the substrate. The effect of doping on the binding energy between hydrogen and these molecules is small in most cases, as can be observed in Table 3. Only for H2 on CLi3 and OLi bonded to Be doped graphene the binding energy is significantly increased. The distance between the hydrogen molecules and the graphene plane is larger in these systems, as compared to the other cases. The gravimetric hydrogen density in the doped graphene systems is determined by the concentration of dopant atoms, since the polylithiated molecules are bonded to these atoms, as well as by the number of hydrogen molecules bonded to a single polylithiated molecule.

The latter is foremost determined by steric hindrance. A Li atom that is close to the graphene plane or to other Li atoms can in general capture only one or two H2 molecules, whereas the ones that are further away from the plane and other Li atoms can bind three H2 molecules. This is illustrated in Figure 5. We have fixed the doping concentration of graphene. In particular for the OLi_m systems one can still increase the doping concentration without introducing too much steric hindrance, which would increase the gravimetric density substantially.

Hydrogen binding energies decrease slightly for hypercoordinated polylithiated molecules, i.e. CLin, n > 3 and OLi_m, m > 1. Figure 5 shows that this leads to a trade-off between hydrogen binding energy and gravimetric density. Nevertheless it is clear that there are several possible

systems and structures that attain a gravimetric density higher than 5% H with H$_2$ binding energies in excess of 0.1 eV.

**Conclusions**

In conclusion, we have shown by means of first-principles DFT calculations that polylithiated molecules can be used as versatile building blocks for hydrogen storage materials. Li–C and Li–O bonds are strongly polar and the partially charged Li atoms can attract up to three to five H$_2$ molecules with an average binding energy in the range 0.10-0.15 eV. CLi$_4$ and OLi$_2$ molecules can then bind 12 and 10 hydrogen molecules, respectively, giving very high gravimetric densities of 37.8 and 40.3 weight % H. Binding polylithiated molecules to carbon nanostructures such as graphene can be used to immobilize them. In particular doping graphene with B or Be increases the binding energy. Although there is a trade-off between the size of the H$_2$ adsorption energy and its gravimetric density in these systems, densities in the range 5-8.5 wt.% H can be reached without seriously decreasing the adsorption energy.
