Determination of the strong coupling constant from the inclusive jet cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV

The experiment used a high-energy proton-antiproton collider with a center-of-mass energy of 1.96 TeV. The data were recorded using a large detector array that included tracking, calorimetric, and muon systems. The analysis focused on the inclusive jet cross section, which is the probability of observing at least one jet in the final state. The jets were identified using the Hijing Monte Carlo simulation, which includes a full description of the detector response.

The measured cross section was found to be in good agreement with the theoretical predictions, which are based on the Lund string model and the JIMMY fragmentation code. The data are consistent with the Standard Model of particle physics, which describes the fundamental forces and particles in the universe.

The results have implications for our understanding of the strong interaction, which is one of the four fundamental forces of nature. The strong coupling constant is a measure of the strength of the strong interaction, and its value is used to test the validity of the Standard Model. The new measurement provides a stringent test of the theory, and may help to guide future theoretical developments.

In conclusion, the experiment has measured the inclusive jet cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV, providing new constraints on the strong coupling constant. The results are consistent with the Standard Model of particle physics, and may help to guide future theoretical developments.

We determine the strong coupling constant $\alpha_s$ and its energy dependence from the $p_T$ dependence of the inclusive jet cross section in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. The strong coupling constant is determined over the transverse momentum range $50 < p_T < 145$ GeV. Using perturbative QCD calculations to order $O(\alpha_3^s)$ combined with $O(\alpha_4)$ contributions from threshold corrections, we obtain $\alpha_s(M_Z) = 0.1161 \pm 0.0048$. This is the most precise result obtained at a hadron-hadron collider.
Asymptotic freedom, the fact that the strong force between quarks and gluons keeps getting weaker when it is probed at increasingly small distances, is a remarkable property of quantum chromodynamics (QCD). This property is reflected by the renormalization group equation (RGE) prediction for the dependence of the strong coupling constant \( \alpha_s \) on the renormalization scale \( \mu_r \) and therefore on the momentum transfer. Experimental tests of asymptotic freedom require precise determinations of \( \alpha_s(\mu_r) \) over a large range of momentum transfer.

Frequently, \( \alpha_s \) has been determined using production rates of hadronic jets in either \( e^+e^- \) annihilation or in deep-inelastic \( ep \) scattering (DIS) [1]. So far there exists only a single \( \alpha_s \) result from inclusive jet production in hadron-hadron collisions. The CDF Collaboration determined \( \alpha_s \) from the inclusive jet cross section in pp collisions at \( \sqrt{s} = 1.8 \) TeV obtaining \( \alpha_s(M_Z) = 0.1178^{+0.0085}_{-0.0095}(\exp) +0.0073(\text{scale}) \pm 0.0059(\text{PDF}) \) [2].

In this article we determine \( \alpha_s \) and its dependence on the momentum transfer using the published measurement of the inclusive jet cross section [3,4] with the D0 detector [5] at the Fermilab Tevatron Collider in pp collisions at \( \sqrt{s} = 1.96 \) TeV. The inclusive jet cross section \( d^2\sigma_{\text{inel}} / dp_T d|y| \) was measured using the Run II iterative midptone cone algorithm [6] with a cone radius of 0.7 in rapidity, \( y \), and azimuthal angle. Rapidity is related to the polar scattering angle \( \theta \) with respect to the beam axis by \( y = 0.5 \ln[(1 + \beta \cos \theta)/(1 - \beta \cos \theta)] \) with \( \beta = |p|/E \). The measurement comprises 110 data points corrected to the particle level [7] and presented as a function of the momentum component transverse to the beam direction, \( p_T \), for \( p_T > 50 \) GeV in six regions of \( |y| \) for \( 0 < |y| < 2.4 \).

The ingredients of perturbative QCD (pQCD) calculations in hadron collisions are \( \alpha_s \), the perturbative coefficients \( c_n \) (in the \( n \)th power of \( \alpha_s \)), and the parton distribution functions (PDFs). Conceptually, PDFs depend only on the hadron momentum fraction \( x \) carried by the parton and on the factorization scale \( \mu_f \). In practice, PDFs are determined from measurements of observables which depend on \( \alpha_s \). Therefore resulting PDF parametrizations depend on the assumption for \( \alpha_s \) made in the extraction procedure. For all precise phenomenology, this implicit \( \alpha_s \) dependence must be taken into account consistently. The pQCD prediction for the inclusive jet cross section can therefore be written as

\[
\sigma_{\text{pert}}(\alpha_s) = \left( \sum_c \alpha_s^2 c_n \right) \otimes f_1(\alpha_s) \otimes f_2(\alpha_s),
\]

where the sum runs over all powers \( n \) of \( \alpha_s \) which contribute to the calculation (\( n = 2, 3, 4 \) in this analysis, see below). The \( f_{1,2} \) are the PDFs of the initial state hadrons and the “\( \otimes \)” sign denotes the convolution over the momentum fractions \( x_1, x_2 \) of the hadrons. Since the RGE uniquely relates the value of \( \alpha_s(\mu_r) \) at any scale \( \mu_r \) to the value of \( \alpha_s(M_Z) \), all equations can be expressed in terms of \( \alpha_s(M_Z) \). The total theory prediction for inclusive jet production is given by the pQCD result in (1) multiplied by a correction factor for nonperturbative effects

\[
\sigma_{\text{theory}}(\alpha_s(M_Z)) = \sigma_{\text{pert}}(\alpha_s(M_Z)) \cdot c_{\text{nonpert}}.
\]

The factor \( c_{\text{nonpert}} \) includes corrections due to hadronization and the underlying events which have been estimated in Ref. [3] using PYTHIA [8] with CTEQ6.5 PDFs [9], tune QW [10], and \( \alpha_s(M_Z) = 0.118 \). The hadronization (underlying event) corrections vary between \(-15\%\) (\(+30\%)\) to \(-3\%\) (\(+6\%)\), for \( p_T = 50 \) to 600 GeV [4].

The perturbative results are the sum of a full calculation to \( \mathcal{O}(\alpha_s^2) \) [next-to-leading order (NLO)], combined with the \( \mathcal{O}(\alpha_s^3) \) (2-loop) terms from threshold corrections [11]. Adding the 2-loop threshold corrections leads to a significant reduction in the \( \mu_r \) and \( \mu_f \) dependence of the calculation. The theory calculations are performed in the MS scheme [12] for five active quark flavors using the next-to-next-to-leading logarithmic (3-loop) approximation of the RGE [13,14]. The PDFs are taken from the MSTW2008 next-to-next-to-leading order (NNLO) parametrizations [15,16] and \( \mu_r \) and \( \mu_f \) are both chosen equal to the jet \( p_T \). The calculations use FASTNLO [17] based on NLOJET++ [18,19] and on code from the authors of Ref. [11].

In this analysis, the value of \( \alpha_s \) is determined from sets of inclusive jet cross section data points by minimizing the \( \chi^2 \) function between data and the theory result (2) using MINUIT [20]. Where appropriate, the \( \alpha_s(M_Z) \) result will be evolved to the scale \( p_T \) using the 3-loop solution of the RGE, providing a result for \( \alpha_s(p_T) \). All correlated experimental and theoretical uncertainties are treated in the Hessian approach [21], except for the \( \mu_r,\mu_f \) dependence (see below). The central \( \alpha_s(M_Z) \) result is obtained by minimizing \( \chi^2 \) with respect to \( \alpha_s(M_Z) \) and the nuisance parameters for the correlated uncertainties. By scanning \( \chi^2 \) as a function of \( \alpha_s(M_Z) \), the uncertainties are obtained from the \( \alpha_s(M_Z) \) values for which \( \chi^2 \) is increased by 1 with respect to the minimum value.

To determine \( \alpha_s \) according to this procedure, knowledge of \( \sigma_{\text{pert}}(\alpha_s(M_Z)) \) is required as a continuous function of \( \alpha_s(M_Z) \), over a \( \alpha_s(M_Z) \) range which covers the possible fit results and their uncertainties. This can be achieved based on a series of PDFs obtained under the same conditions but for different values of \( \alpha_s(M_Z) \) using interpolation in \( \alpha_s(M_Z) \). Some recent PDF analyses have applied this strategy and their results are documented for different values of \( \alpha_s(M_Z) \). The MSTW2008 NNLO (NLO) PDF parametrizations [15,16] are presented for 21 \( \alpha_s(M_Z) \) values in the range 0.107–0.127 (0.110–0.130) in steps of 0.001 and the CTEQ6.6 results [22] are available for five values of \( \alpha_s(M_Z) = 0.112, 0.114, 0.118, 0.122, 0.125 \). Because of the wide range in \( \alpha_s(M_Z) \) covered by the MSTW2008 PDFs and the fine and equidistant spacing in \( \alpha_s(M_Z) \), we use cubic spline interpolation to obtain a smooth parametrization for the \( \alpha_s(M_Z) \) dependence of
the cross section for $0.108 \leq \alpha_s(M_2) \leq 0.126$ ($0.111 \leq \alpha_s(M_2) \leq 0.129$) for the NNLO (NLO) PDFs. This range is sufficient to cover our central values and the uncertainties. The MSTW2008 analysis includes data sets that have not yet been included in other global PDF analyses (DIS jet data from HERA and recent CCFR/NuTeV dimuon data); the results are available in NNLO accuracy which is adequate when including the $O(\alpha_s^4)$ contributions from threshold corrections in the cross section calculation. The CTEQ6.6 PDF parametrizations are available up to NLO, for five $\alpha_s(M_2)$ values, and for a more limited range in $\alpha_s(M_2)$ as compared to MSTW2008. Therefore the MSTW2008 PDFs are used to obtain the main results for this analysis while the CTEQ6.6 PDFs are used for comparison.

Care must be taken in phenomenological analyses if the observable under study was already used to provide significant constraints on the PDFs as this introduces correlations of experimental and PDF uncertainties, and it may affect the sensitivity to possible new physics signals. Both aspects are relevant in this $\alpha_s$ determination since the D0 inclusive jet data under study is included in the MSTW2008 PDF analysis. Since the correlation of experimental and PDF uncertainties is not documented, it cannot be taken into account when using the PDFs to extract $\alpha_s(M_2)$ from the jet data. As a consequence, we must avoid using those jet cross section data points which have provided strong PDF constraints. While the quark PDFs are constrained by precision structure function data, the only direct source of information on the high $x$ gluon PDF comes currently from Tevatron inclusive jet data. The impact of Tevatron jet data on the gluon density is documented in Ref. [15] in Figs. 51–53. Figure 51 shows that excluding the Tevatron jet data starts to affect the gluon density at $x > 0.2$–0.3, while for $x \approx 0.25$ the difference in the gluon density with and without Tevatron jet data is less than 5%. Figure 53 shows that $x < 0.3$ is the region in which the gluon results for MSTW2008 and CTEQ6.6 are very close. We conclude that for momentum fractions $x < 0.2$–0.3 the Tevatron jet data do not have a significant impact on the gluon density, and therefore we can neglect correlations between PDF and experimental uncertainties for these data. Based on this constraint we select below those inclusive jet data points from which we extract $\alpha_s$.

The Tevatron jet data (which access $p_T$ above 500 GeV) are probing momentum transfers at which $\alpha_s$ has not yet been probed in other experiments. Therefore we cannot rule out deviations in the running of $\alpha_s$ at large momentum due to possible new physics contributions to the RGE. Since such modifications of the RGE are not taken into account in the PDF determinations, these effects would effectively be absorbed into the PDFs. By construction, using such PDFs to extract $\alpha_s$ could seemingly confirm the RGE expectations, even in the presence of new physics contributions to the RGE. For a consistent $\alpha_s$ determination we would therefore exclude high $p_T$ data in the region where the RGE has not yet been successfully tested which is the region of $p_T \approx 200$ GeV [1]. However, those data are already removed by the restriction to $x < 0.2$–0.3, so no additional requirement is needed to account for this.

In $2 \rightarrow 2$ processes, given the rapidities and $p_T$ of the two jets, one can compute the momentum fractions $x_1$ and $x_2$ carried by the initial partons. The inclusive jet cross section at given $p_T$ and $|y|$ is, however, integrated over all additional jets in an event, so the rapidity of the other jet and therefore the full event kinematics, including $x_1$ and $x_2$, are not known. The value of the larger momentum fraction $x_{\text{max}} = \max(x_1, x_2)$ can be computed only under an assumption for the rapidity of the unobserved jet. For each inclusive jet $(p_T, |y|)$ bin we define the variable $\tilde{x} = x_T \cdot (e^{|y|} + 1)/2$ where $x_T = 2p_T/\sqrt{s}$, $p_T$ is taken at the bin center, and $|y|$ at the lower boundary of the $|y|$ bin. This variable $\tilde{x}$ corresponds to $x_{\text{max}}$ for the case that the unobserved jet was produced at $y = 0$. In the pQCD calculation, for a given inclusive jet $(p_T, |y|)$ bin the distribution of $x_{\text{max}} = \max(x_1, x_2)$ always has a peak plus a tail towards high $x_{\text{max}}$ values. Although the variable $\tilde{x}$ does not represent the peak position of the $x_{\text{max}}$ distribution, it is correlated with that distribution. The requirement $\tilde{x} < 0.15$ removes all data points for which more than half of the cross section is produced at $x_{\text{max}} \geq 0.25$. This leaves 22 (out of 110) data points for the $\alpha_s$ analysis with $p_T < 145$ GeV for $0 < |y| < 0.4$, $p_T < 120$ GeV for $0.4 < |y| < 0.8$, $p_T < 90$ GeV for $0.8 < |y| < 1.2$, and $p_T < 70$ GeV for $1.2 < |y| < 1.6$. Although this selection criterion is well motivated, the specific choices of the variable $\tilde{x}$ and the requirement $\tilde{x} < 0.15$ are somewhat arbitrary. We have therefore studied variations of the selection requirement in the range $\tilde{x} < 0.10$–0.17 and other choices for the definition of $\tilde{x}$ (for example assuming that the unobserved jet has $y_2 = \pm |y|$), and, we find that the $\alpha_s$ results are stable within 1%. We conclude that the choice of $\tilde{x} < 0.15$ restricts the jet data to those points which receive no significant contributions from $x_{\text{max}} > 0.25$. For these data points, experimental and PDF uncertainties are treated as being uncorrelated.

In the $\alpha_s$ determination, we consider the uncorrelated experimental uncertainties and all 23 sources of correlated experimental uncertainties as documented in Refs. [3,4]. The nonperturbative corrections are divided into hadronization and underlying event effects. The uncertainty for each is taken to be half the size of the corresponding effect. PDF uncertainties are computed using the 20 68% C.L. uncertainty eigenvectors as provided by MSTW2008 [15]. The uncertainties in the pQCD calculation due to uncalculated higher order contributions are estimated from the $\mu_r, \mu_f$ dependence of the calculations when varying the scales in the range $0.5 < \mu_r, \mu_f < 2$. In the kinematic region under study, variations of $\mu_r$ and $\mu_f$ have positively corre-
lated effects on the jet cross sections. A correlated variation of both scales is therefore a conservative estimate of the corresponding uncertainty. Since the $\mu_{r,f}$ uncertainties cannot be treated as Gaussian, these are not included in the Hessian $\chi^2$ definition. Following Refs. [23,24], the $\alpha_s$ fits are repeated for different choices ($\mu_{r,f} = 0.5 p_T$ and $\mu_{r,f} = 2 p_T$) and the differences to the central result (obtained for $\mu_{r,f} = p_T$) are taken to be the corresponding uncertainties for $\alpha_s(M_Z)$. Those are added in quadrature to the other uncertainties to obtain the total uncertainty.

Data points from different $|y|$ regions with similar $p_T$ are grouped to determine the results for $\alpha_s(M_Z)$ and $\alpha_s(p_T)$. A combined fit to all 22 data points yields $\alpha_s(M_Z) = 0.1161^{+0.0048}_{-0.0048}$ with $\chi^2/N_{\text{dof}} = 17.2/21$. The results are shown in Fig. 1 as nine $\alpha_s(p_T)$ (top) and $\alpha_s(M_Z)$ values (bottom) in the range $50 < p_T < 145$ GeV with their total uncertainties which are largely correlated between the points. Also included are results at lower $p_T$ from inclusive jet cross sections in DIS from the HERA experiments H1 [23] and ZEUS [24] and the 3-loop RGE prediction for our combined $\alpha_s(M_Z)$ result. Our $\alpha_s(p_T)$ results are consistent with the energy dependence predicted by the RGE and extend the HERA results towards higher $p_T$. The combined result is consistent with the result of $\alpha_s(M_Z) = 0.1189 \pm 0.0032$ from combined HERA jet data [25] and with the world average value of $\alpha_s(M_Z) = 0.1184 \pm 0.0007$ [1]. The contributions from individual uncertainty sources are listed in Table I. The largest source is the experimental correlated uncertainty for which the dominant contributions are from the jet energy calibration, the $p_T$ resolution and the integrated luminosity.

Varying the size of the uncertainties of the nonperturbative corrections between a factor of 0.5 and 2 changes the central value by $+0.0003$ and does not affect the uncertainty of the combined $\alpha_s(M_Z)$ result. Replacing the MSTW2008 NNLO PDFs by the CTEQ6.6 PDFs changes the central result by only $+0.5\%$ which is much less than the PDF uncertainty. Excluding the 2-loop contributions from threshold corrections and using pure NLO pQCD (together with MSTW2008 NLO PDFs and the 2-loop RGE) gives a result of $\alpha_s(M_Z) = 0.1202^{+0.0072}_{-0.0050}$. The small increase in the central value is a result of the missing $O(\alpha_s^3)$ contributions which are compensated by a corresponding increase in $\alpha_s$. The difference to the central result is well within the scale uncertainty of the NLO result. The increased uncertainty is mainly caused by the increased $\mu_{r,f}$ dependence, but also by the larger PDF uncertainty at NLO.

In summary, we have determined the strong coupling constant from the inclusive jet cross section using theory prediction in NLO plus 2-loop threshold corrections. The $\alpha_s(p_T)$ results support the energy dependence predicted by the renormalization group equation. The combined result from 22 selected data points is $\alpha_s(M_Z) = 0.1161^{+0.0048}_{-0.0048}$.

---

**TABLE I.** Central values and uncertainties due to different sources for the nine $\alpha_s(p_T)$ results and for the combined $\alpha_s(M_Z)$ result (bottom). All uncertainties are multiplied by a factor of $10^3$.
