Individual variability in reward-based learning has been ascribed to quantitative variation in baseline levels of striatal dopamine. However, direct evidence for this pervasive hypothesis has hitherto been unavailable. We demonstrate that individual differences in reward-based reversal learning reflect variation in baseline striatal dopamine synthesis capacity, as measured with neurochemical positron emission tomography. Subjects with high baseline dopamine synthesis in the striatum showed relatively better reversal learning from unexpected rewards than from unexpected punishments, whereas subjects with low baseline dopamine synthesis in the striatum showed the reverse pattern. In addition, baseline dopamine synthesis predicted the direction of dopaminergic drug effects. The D2 receptor agonist bromocriptine improved reward-based relative to punishment-based reversal learning in subjects with low baseline dopamine synthesis capacity, while impairing it in subjects with high baseline dopamine synthesis capacity in the striatum. Finally, this pattern of drug effects was outcome-specific, and driven primarily by drug effects on punishment-, but not reward-based reversal learning. These data demonstrate that the effects of D2 receptor stimulation on reversal learning in humans depend on task demands and baseline striatal dopamine synthesis capacity.

Key words: dopamine; reward; punishment; striatum; PET; learning

Introduction

Adaptation to our environment requires the anticipation of biologically relevant events by learning signals of their occurrence, i.e., reward-based learning. Models of reward-based learning use a prediction error signal, representing the difference between expected and obtained events, to update their predictions based on the environment (Sutton and Barto, 1998). A putative mechanism of the prediction error signal for reward is the phasic firing of dopamine neurons in the midbrain (Montague et al., 1996; Schultz et al., 1997). These neurons innervate large parts of the brain, including the striatum, the major input structure of the basal ganglia. In keeping with this anatomical arrangement, the striatum has often been implicated in reward-based learning and its modulation by dopamine (Cools and Robbins, 2004; Frank, 2005; Pessiglione et al., 2006; Schönberg et al., 2007) and reward-based learning is modulated by agonists of D2/D3 receptors that are abundant in the striatum (Frank and O’Reilly, 2006; Pizzagalli et al., 2008). Schönberg et al. (2007) have recently proposed that individual differences in reward-based learning may reflect differences in striatal dopamine function. However, there is no direct evidence for this hypothesis. Here we demonstrate a significant positive relationship between reward-based learning and baseline striatal dopamine synthesis capacity, as measured with uptake of the positron emission tomography (PET) tracer [18F]fluorometatyrosine (FMT).

We further establish the link between dopamine in the striatum and reward-based learning by showing that effects of dopamine D2 receptor stimulation also depend on baseline striatal dopamine synthesis capacity. Evidence from studies with experimental animals (Williams and Goldman-Rakic, 1995; Zahr et al., 1997; Arnsten, 1998) has revealed an “inverted U”-shaped relationship between D1 receptor stimulation in the prefrontal cortex and cognitive performance. This relationship has been related to baseline-dependency of drug effects, so that low baseline dopamine levels are remedied, while high baseline dopamine levels are detrimentally over-dosed by the same dopamine D1 receptor agonist (Phillips et al., 2004). Although recent studies with humans, which have made use of genetic variation in the D2...
receptor gene, have suggested that a similar mechanism might underlie contrasting effects of D2 receptor stimulation in the striatum on reward-based learning (Frank and O’Reilly, 2006; Cohen et al., 2007), direct evidence for baseline-dependency of dopaminergic drug effects on reward-learning in the striatum is lacking. We combined neurochemical PET imaging with behavioral psychopharmacology to test this hypothesis. We studied the effects of a single oral dose (1.25 mg) of the dopamine D2 receptor agonist bromocriptine on reversal learning in young healthy volunteers, who also, on a separate occasion, underwent a PET scan with the tracer FMT. Subjects with low synthesis capacity were predicted to benefit from D2 receptor stimulation with bromocriptine, while subjects with high synthesis capacity were predicted to be detrimentally overdosed by the same drug.

We used a reversal learning paradigm that enabled the separate assessment of reward- and punishment-based reversal learning (Cools et al., 2008a). Based on prior data indicating that dopaminergic drug effects are outcome-specific (Cools et al., 2006), we anticipated contrasting effects of bromocriptine on reward- and punishment-based reversal learning.

Materials and Methods

General procedure. The University of California Berkeley Committee for the Protection of Human Subjects approved the procedures, which were in accord with the Helsinki Declaration of 1975.

Eleven subjects [all female; mean (SD) age = 22.2 (2.0)] underwent a single PET scan with the tracer 6-[18F]fluoro-l-m-tyrosine (FMT). The PET data from these subjects were previously reported in relation to their working memory capacity as measured with the listening span test (Cools et al., 2008b). Detailed neuropsychological characteristics of the subjects are presented in that previous paper. All subjects were screened for psychiatric and neurological disorders; exclusion criteria were any history of cardiac, hepatic, renal, pulmonary, neurological, psychiatric or gastrointestinal disorders, an episode of loss of consciousness, use of psychoactive drugs, or maternal smoking during pregnancy. All subjects were asked to refrain from caffeine and cigarettes on the days of testing.

PET imaging and analysis. FMT is a substrate of l-aromatic amino acid decarboxylase and an index of presynaptic dopamine synthesis capacity, i.e., processes that occur in striatal terminal midbrain dopamine neurons. The tracer was synthesized with a modification of the procedure as previously reported (Namavari et al., 1993). Scanning procedures, data analysis and region of interest procedures were also as previously reported (Cools et al., 2008b).

All subjects were scanned ~60 min after administration of an oral dose of 2.5 mg/kg of the peripheral decarboxylase inhibitor carbidopa to increase brain uptake of the tracer. Participants were positioned on the scanner bed with a pillow and an elastic band to comfortably restrict head motion. Images (voxel size was 3.6 * 3.6 mm in-plane with 4 mm slice thickness) were obtained on a Siemens ECAT EXACT HR scanner in 3D acquisition mode. A 10 min transmission scan was obtained for attenuation correction, then ~2.5 mCi of FMT were subsequently injected as a bolus in an antecubital vein and a dynamic acquisition sequence in 3D mode was obtained: 4 * 1 min, 3 * 2 min, 3 * 3 min, 14 * 5 min for a total of 89 min of scan time.

Data were reconstructed using an ordered subset expectation maximization (OSEM) algorithm with weighted attenuation, an image size of 256 × 256, and 6 iterations with 16 subsets. A Gaussian filter with 6 mm FWHM was applied, with a scatter correction. Images were evaluated for subject motion and realigned as necessary using algorithms implemented in SPM2.

Structural scans (high-resolution MP-FLASH; 0.875 × 0.875 × 1.54 mm) were obtained during the prior magnetic resonance imaging (MRI) study (structural scans were not available for two out of 11 subjects). This permitted the use of the high-resolution MRI image for anatomical verification of the localization of functional PET regions of interest (ROIs). Bilateral cerebellar ROIs (10 mm spheres) were used as a reference ROI in conjunction with ROIs in striatum and a simplified reference tissue model with a graphical analysis approach (Patlak and Blasberg, 1985; Lammertsma and Hume, 1996). This leads to an influx constant K, which reflects regional FMT uptake scaled to the volume of distribution in the reference region.

To test hypotheses about differences in subregions of the striatum, we defined ROIs in the right and left caudate and putamen. An axial image representing the sum of the last four emission scans of the PET scanning session (4 × 5 min frames) was coregistered to the high-resolution MR scan using a 12-parameter affine algorithm implemented in SPM2. ROIs were drawn on these images (Wang et al., 1996; Volkow et al., 1998), using the atlas of Talairach and Tournoux (Talairach and Tournoux, 1988) to delineate the caudate and putamen. Regions were drawn on data in native space to preserve differences in tracer uptake due to anatomical variability between subjects. We have previously demonstrated the ability to draw ROIs with high inter-rater reliability (Klein et al., 1997). The Patlak model was fitted with dynamic data from each ROI from 24 to 89 min, when the regression is highly linear (r > 0.99).

It might be noted that there was a delay between the acquisition of the PET data and that of the behavioral data (mean 16.7 months; SD 2.4 months). Uptake of the tracer [18F]fluorodopa and tyrosine is thought to...
reflect a relatively stable process (synthesis capacity) that is not particularly sensitive to small state-related changes, much like uptake of the tracer F-DOPA. Thus, a study by Vingerhoets et al. (1994) demonstrated that striatal \( K_i \) is a reliable measurement, with it having a 95% chance of lying within 18% of its value within an individual normal subject. We argue that the delay does not confound our results, but rather renders them more striking. Any instability in the PET measurement across the delay would have reduced rather than enhanced the likelihood of obtaining the results, which were statistically controlled for noise by an \( \alpha \) level of 0.05. Data analyses supported this hypothesis, as the effects were stronger when effects of interest were corrected for the delay between the two sessions than when they were not. Here we report only those analyses in which we corrected for the delay, by entering it as a covariate, although all effects were also significant when they were not corrected for the delay. Furthermore, in the supplemental Results C (available at www.jneurosci.org as supplemental material), we report an additional analysis, explicitly addressing in a quantitative manner the possibility that the effect reflects noise.

**Experimental paradigm.** The task required the learning and reversal of predictions of reward and punishment. On each trial two vertically adjacent stimuli were presented: one face and one scene; location randomized; about 19 inch viewing distance; subtending \( -3^\circ \) horizontally and \( 3.5^\circ \) vertically. One of the stimuli was associated with reward, while the other was associated with punishment. On each trial, one of the two stimuli was highlighted with a black border surrounding the stimulus and subjects had to predict, based on trial and error learning, whether the highlighted stimulus would lead to reward or punishment. Subjects indicated their predictions by pressing, with the index or middle finger, one of two colored buttons (corresponding to keys “b” and “n” depending on the response-outcome mapping) on a laptop keyboard. They pressed the green button for reward and the red button for punishment. The outcome-response mappings were counterbalanced between subjects. The (self-paced) response was followed by an interval of 1000 ms, after which the outcome was presented for 500 ms. Note that this outcome did not provide direct performance feedback. Reward consisted of a green smiley face, a “+ $100” sign and a high-frequency jingle tone. Punishment consisted of a red sad face, a “– $100” sign and a single low-frequency tone. After the outcome, the screen was cleared for 500 ms, after which the next two stimuli were presented. The stimulus-outcome contingencies reversed multiple times provided learning criteria were met.

Each subject performed one practice block and four experimental blocks. Each practice block consisted of one acquisition stage and one reversal stage (learning criterion was 20 [not necessarily consecutive] correct trials). Each experimental block consisted of one acquisition stage and eight reversals, with the number of reversals per stage determined by a pre-set learning criterion. Learning criteria (i.e., the number of consecutive correct trials following which the contingencies reversed) varied between stages (mean = 6.9; SD = 1.8; range from 5 to 9), to prevent predictability of reversals. The maximum number of reversal stages per experimental block was 16, although the block terminated automatically after completion of 120 trials (≈ 6.6 min), so that each subject performed 480 trials (4 blocks) per experimental session. The mean number of stages completed is reported in supplemental Table 1, available at www.jneurosci.org as supplemental material.

The task consisted of two conditions (two blocks per condition). In the unexpected reward condition, reversals were signaled by unexpected reward occurring after the previously punished stimulus was highlighted. Conversely, in the unexpected punishment condition, reversals were signaled by unexpected punishment following the previously rewarded stimulus. Accuracy on the trial following the unexpected outcome (“switch trials”) reflected the degree to which subjects updated their predictions based on unexpected outcomes. The stimulus that was highlighted on the first trial of each reversal stage (on which the unexpected outcome was presented) was always highlighted again on the second trial of that stage (i.e., the switch trial on which the subject had to implement the reversed contingencies and switch their predictions).

Results

In our sample of young healthy volunteers, influx constant \( K_i \) values varied between 0.018 and 0.027, falling well within the range of “normal” values observed previously (Eberling et al., 2007). Subjects performed well on the reversal learning task, with an average accuracy rate on trials after the unexpected outcomes >90% (supplemental Table 2, available at www.jneurosci.org as supplemental material).

First, we analyzed the data from the placebo session. A repeated measures ANOVA was conducted with valence as the within-subject factor and dopamine synthesis capacity as a covariate. The delay between acquisition of the drug and PET data was also entered as a covariate. Pearson product-moment correlation coefficients were calculated between \( K_i \)-values extracted from ROIs and behavioral data. All correlations represent partial correlations, correcting for the delay between PET and drug data acquisition. All correlations were also significant without this correction. The distribution of none of the parameters assessed here deviated from normality as indicated by Kolmogorov–Smirnov tests (all \( p = 0.2 \)).

All reported \( p \) values are two-tailed.

Based on prior data (Frank et al., 2004; Cools et al., 2006; Frank and O’Reilly, 2006), we predicted that bromocriptine would have contrasting effects on reward- and punishment-based reversal learning. Following this prior work, we were specifically interested in the drug effect on the balance between (reversal) learning from reward and from punishment. Therefore, relative reversal learning scores were calculated, by which accuracy scores on punishment-based switch trials were subtracted from accuracy scores on reward-based switch trials. The additional advantage of this method is that it controls for within-subject variability due to other factors such as arousal, attention and motivation, which would have affected each measure in the same direction. Thus, general effects of the drug that were not specific to the ability to learn from reward or punishment were subtracted out. Further, we report drug effects (differences between the placebo and the bromocriptine session), because it is these drug effects that are of primary interest in the present study. Finally, we also report reward- and punishment-based reversal learning under placebo and under bromocriptine separately.

**Statistical analysis.** Mean proportions of correct responses on the learning task were calculated as reported previously (Cools et al., 2006, 2008a). Repeated measures ANOVAs were conducted using SPSS 15.0 with drug and valence as within-subject factors and dopamine synthesis capacity as a covariate. The delay between acquisition of the drug and PET data was also entered as a covariate. Pearson product-moment correlation coefficients were calculated between \( K_i \)-values extracted from ROIs and behavioral data. All correlations represent partial correlations, correcting for the delay between PET and drug data acquisition. All correlations were also significant without this correction. The distribution of none of the parameters assessed here deviated from normality as indicated by Kolmogorov–Smirnov tests (all \( p = 0.2 \)).

All reported \( p \) values are two-tailed.

**Results**

In our sample of young healthy volunteers, influx constant \( K_i \) values varied between 0.018 and 0.027, falling well within the range of “normal” values observed previously (Eberling et al., 2007). Subjects performed well on the reversal learning task, with an average accuracy rate on trials after the unexpected outcomes >90% (supplemental Table 2, available at www.jneurosci.org as supplemental material).

First, we analyzed the data from the placebo session. A repeated measures ANOVA was conducted with valence as the within-subject factor and dopamine synthesis capacity and acquisition delay as covariates. Consistent with neurophysiological evidence from nonhuman primates (Hollerman and Schultz, 1998), this analysis revealed a highly significant interaction between valence and synthesis capacity (\( F_{(1,8)} = 19.0, p = 0.002 \)) and no effects of acquisition delay. This interaction reflected a positive correlation between dopamine synthesis capacity in the striatum and reversal learning from reward relative to punishment under placebo (Fig. 2a). It was present across the entire striatum (averaged across right and left caudate nucleus and putamen; \( r = 0.84, p = 0.004 \)), and also within striatal subregions (bilateral caudate nucleus: \( r = 0.8, p = 0.007 \); bilateral putamen: \( r = 0.87, p = 0.001 \)). The correlation between dopamine synthesis capacity and relative performance on non-switch trials (trials requiring reward-prediction minus trials requiring punishment-prediction) was also positive, albeit non-significant (entire striatum: \( r = 0.54, p = 0.1 \)).

The positive correlation between synthesis capacity and relative reversal learning scores (i.e., the difference between reward and punishment) was driven by a positive correlation between synthesis capacity and reward-based reversal under placebo (accuracy: \( r = 0.79, p = 0.007 \)), indicating that greater dopamine synthesis capacity predicted better reward-based reversal. Conversely, punishment-based reversal under placebo did not depend on baseline dopamine synthesis capacity (accuracy: \( r = 0.20 \)).
capacity also predicted the effects of the dopamine D2 receptor (Hollerman and Schultz, 1998). 

mine firing that accompanies unexpected reward omission 

unexpected punishment suggests that synthesis capacity did not 

ences the efficacy of impulse-dependent phasic dopamine 

agion bromocriptine on reversal learning. To this end, we con-

Figure 2. Baseline dependency of relative reversal learning scores and their sensitivity to D2

B. Negative correlation between the effect of bromocriptine on relative reversal learning and striatal dopamine synthesis capacity.

−0.2, p = 0.6) (Fig. 3a,b). This finding is remarkably consistent 

with neurophysiological evidence for associations between pha-

sic dopamine burst firing and reward prediction error (Holler-

man and Schultz, 1998), given that synthesis capacity likely influences the efficacy of impulse-dependent phasic dopamine 

release. The finding that the effect did not extend to learning from unexpected punishment suggests that synthesis capacity did not influence the efficacy of the impulse-dependent pause in dopamine firing that accompanies unexpected reward omission (Hollerman and Schultz, 1998).

Next we assessed whether baseline striatal dopamine synthesis capacity also predicted the effects of the dopamine D2 receptor agonist bromocriptine on reversal learning. To this end, we conducted a repeated measures ANOVA with drug and valence as within-subject factors and dopamine synthesis capacity and acquisition delay as covariates. As predicted, this analysis revealed highly significant two-way drug by valence (F(1,7) = 17.4, p = 0.004) and three-way drug by valence by synthesis capacity interactions (F(1,7) = 29.4, p = 0.001). There were no main effects (acquisition delay: F(1,7) = 0.2, p = 0.7; synthesis capacity: F(1,7) = 3.0, p = 0.1; valence: F(1,7) = 0.8, p = 0.4; drug: F(1,7) = 0.03, p = 0.9) and no other interaction effects (valence by synthesis capacity: F(1,7) = 0.6, p = 0.5; valence by delay: F(1,7) = 0.3, p = 0.6; drug by synthesis capacity: F(1,7) = 0.2, p = 0.7; drug by delay: F(1,7) = 0.003, p = 0.96; drug by valence by delay: F(1,7) = 2.4, p = 0.2). The significant three-way interaction reflected a significant negative correlation between synthesis capacity and drug-induced improvement on relative reversal learning scores (r2 = −0.9, p = 0.001) (Fig. 2b). Consistent with an ‘inverted u’-shaped dose–response curve, bromocriptine improved reward-based reversal relative to punishment-based reversal in subjects with low baseline levels of striatal dopamine synthesis capacity, but had the reverse effect in subjects with high baseline levels. Again the effect extended across striatal subregions (bilateral caudate nucleus: r7 = −0.89, p = 0.001; bilateral putamen: r7 = −0.89, p = 0.001). The correlation with (relative) performance on non-switch trials was not significant (r7 = −0.45, p = 0.2).

Breakdown of the three-way interaction effect into simple interaction effects for reward and punishment separately revealed a significant interaction between drug and synthesis capacity for punishment-based reversal (F(1,6) = 14.2, p = 0.007), as well as a near-significant interaction between drug and synthesis capacity for reward-based reversal (F(1,8) = 3.4, p = 0.1). These interactions reflected a highly significant positive correlation between striatal dopamine synthesis and drug-induced improvement in punishment-based reversal (r7 = 0.8, p = 0.007) (Fig. 3b,d,f), while the negative correlation between dopamine synthesis and drug effects on reward-based reversal was less convincing (r6 = −0.55, p = 0.1) (Fig. 3a,e).

In supplementary analyses, we aimed to disentangle two alternative hypotheses regarding dopaminergic modulation. Specifically, to establish whether the here described effects reflect a modulation of learning or switching, we applied computational reinforcement learning algorithms to fit individual subjects’ trial-by-trial sequence of choices (Sutton and Barto, 1998; Frank et al., 2007b). These algorithms allowed us to generate learning-rate parameters (separately for reward and punishment) that were not directly observable in the behavioral data. Detailed methods and results are presented in the supplemental Materials, available at www.jneurosci.org. Critically, a significant relationship was obtained between dopamine synthesis and the drug effect on reward learning rate (r6 = −0.71, p = 0.02), as well as between dopamine synthesis and the drug effect on punishment learning rate (r6 = 0.78, p = 0.01) (supplemental Figure and Table 3, available at www.jneurosci.org as supplemental material).

In summary, higher dopamine synthesis capacity in the striatum was associated with better reward-based reversal learning under placebo. Furthermore, bromocriptine improved reward-based reversal learning in subjects with low synthesis capacity, while impairing it in subjects with high synthesis capacity. Conversely, the same drug dose impaired punishment-based reversal learning in subjects with low synthesis capacity, while improving it in subjects with high synthesis capacity.

Discussion

Baseline dopamine measures predicted reversal learning due to reward prediction errors relative to punishment prediction errors. The result provides the first empirical evidence for the pervasive, but hitherto untested hypothesis that individual variation in reward-based learning reflects quantitative variation in baseline levels of striatal dopamine function, as indexed by uptake of a PET dopamine synthesis tracer. Critically, the effect was outcome-specific, so that high dopamine synthesis was associated with a bias toward reward- relative to punishment-based reversal learning. This observation concurs with recent theoretical mod-
dose–response curve might reflect differential stimulation of pre- versus postsynaptic D₂ receptors in high- versus low-baseline subjects respectively. Specifically, we hypothesize that the established self-regulatory mechanism of presynaptic action of bromocriptine, by which dopamine cell firing, release and/or synthesis are inhibited, is more pronounced in subjects with already high baseline levels of synaptic dopamine than in subjects with low baseline levels of dopamine. Furthermore, disproportionate efficacy of self-regulatory (presynaptic) mechanisms in high-baseline subjects might be accompanied by desensitization of postsynaptic D₂ receptors, thereby further reducing the postsynaptic efficacy of bromocriptine. Thus bromocriptine might have paradoxically reduced synaptic dopamine levels, thereby impairing reward-based learning, via a presynaptic mechanism of action in high-baseline subjects. Conversely, we hypothesize that the same drug enhanced reward-based learning by increasing dopamine transmission via a postsynaptic mechanism of action in low-baseline subjects.

The effects likely reflect general associative learning from unexpected outcomes rather than switching per se, as demonstrated by the supplementary model-based analyses. Although the rapid updating required in the current task, on which subjects expressed high learning rates, is different from the slower types of incremental probabilistic learning (Cools et al., 2001; Frank et al., 2004), which require the integration of outcomes across more distant histories, we hypothesize that similar associations will be observed between striatal dopamine synthesis and updating during slow learning. Consistent with this hypothesis is the observation that effects of dopaminergic manipulations on incremental positive reinforcement learning correlate with effects on rapid working memory updating (Frank and O’Reilly, 2006; Frank et al., 2007a), suggestive of similar dopaminergic influences on parallel neurobiological circuits.

One potential caveat of the present study is the considerable delay between the acquisition of the PET data and that of the behavioral data. We argue that this delay does not confound our results for the following reasons. First, there is evidence that measures of dopamine synthesis capacity are relatively stable in healthy volunteers, even across many years. Specifically, Vingerhoets et al. (1994b) have shown that the fluorodopa PET index decreased non-significantly over seven years by 0.3% per year. In addition, the reliability of change coefficient was 96%, confirming their previous study showing that striatal activity measured by PET is a highly reproducible measurement (Vingerhoets et al., 1994a), although we acknowledge that our age group was younger than the one studied by Vingerhoets et al. Second, the effects were statistically controlled for noise by an α level of 0.05

Figure 3. Baseline dependency of absolute reversal learning scores and their sensitivity to D₂ receptor stimulation. A, Significant positive correlation between striatal dopamine synthesis capacity (K-values) and reward-based reversal learning under placebo. D, Significant positive correlation between striatal dopamine synthesis capacity and punishment-based reversal learning under bromocriptine (p = 0.015). E, Nonsignificant negative correlation between striatal dopamine synthesis capacity and the effect of bromocriptine on reward-based reversal learning (bromocriptine minus placebo). F, Significant positive correlation between striatal dopamine synthesis capacity and the effect of bromocriptine on punishment-based reversal learning (bromocriptine minus placebo). For statistics, see Results.

els and empirical work (Frank et al., 2004, 2005). For example, patients with Parkinson’s disease, which is characterized by severe dopamine depletion in the striatum, exhibit difficulty with learning from reward relative to punishment, as measured with the present paradigm (Cools et al., 2006) as well as with a probabilistic selection task (Frank et al., 2004). Furthermore, the common dopamine-enhancing antiparkinson medication reversed this bias, leading to difficulty with learning from punishment relative to reward (Cools et al., 2006; Frank et al., 2004). The present data demonstrate that individual differences in baseline levels of dopamine in the healthy population also predict reward-relative to punishment-learning biases.

Perhaps most critically, this work provides the first direct evidence for the existence of an inverted u-shaped relationship between striatal function and dopamine D₂ receptor stimulation. Based on evidence from experimental animals (Skirboll et al., 1979; Torstenson et al., 1998), we argue that this curvilinear relationship correlates with effects on rapid working memory updating (Frank and O’Reilly, 2006; Frank et al., 2007a), suggestive of similar dopaminergic influences on parallel neurobiological circuits.
and remained highly significant after statistical correction for the acquisition delay. Finally, any instability in the PET measurement across the delay would have reduced rather than enhanced the likelihood of obtaining the result. There is a possibility that, if there had been no delay, the correlation between synthesis capacities and remained highly significant after statistical correction for the spatial location.

Our data elucidate not only a fundamental mechanism underlying the behavioral role of striatal dopamine, but also identify an important neurobiological factor, i.e., baseline striatal dopamine synthesis that contributes to the large variability in dopaminergic drug efficacy. This finding should have far-reaching implications for individualized drug development in neuropsychiatry, where variable drug efficacy provides a major problem for the treatment of patients with heterogeneous spectrum disorders like schizophrenia, attention deficit/hyperactivity disorder and drug addiction.
