Abstract

**Background:** Studies on the myotonic dystrophy protein kinase (DMPK) gene and gene products have thus far mainly concentrated on the fate of length mutation in the (CTG)n repeat at the DNA level and consequences of repeat expansion at the RNA level in DM1 patients and disease models. Surprisingly little is known about the function of DMPK protein products.

**Methodology/Principal Findings:** We demonstrate here that transient expression of one major protein product of the human gene, the hDMPK A isoform with a long tail anchor, results in mitochondrial fragmentation and clustering in the perinuclear region. Clustering occurred in a variety of cell types and was enhanced by an intact tubulin cytoskeleton. In addition to morphomechanical changes, hDMPK A expression induces physiological changes like loss of mitochondrial membrane potential, increased autophagy activity, and leakage of cytochrome c from the mitochondrial intermembrane space accompanied by apoptosis. Truncation analysis using YFP-hDMPK A fusion constructs revealed that the protein’s tail domain was necessary and sufficient to evoke mitochondrial clustering behavior.

**Conclusion/Significance:** Our data suggest that the expression level of the DMPK A isoform needs to be tightly controlled in cells where the hDMPK gene is expressed. We speculate that aberrant splice isoform expression might be a codetermining factor in manifestation of specific DM1 features in patients.

Introduction

The myotonic dystrophy protein kinase (DMPK) gene is involved in myotonic dystrophy type I (DM1) when it is mutant and contains an unstable (CTG)n segment in its 3’ terminal exon [1]. DMPK encodes several serine/threonine protein kinases, believed to be involved in ion homeostasis and remodeling of the actin cytoskeleton [2–5]. Up till now, emphasis in most DM1 studies was on the pathobiological significance of toxic RNA products from the mutant DMPK gene. Only relatively few studies have addressed individual protein products from the DMPK gene, including their normal structure function relationship [6,7].

Constitutive and regulated modes of alternative splicing exist for DMPK pre-mRNA and result in the expression of six major DMPK splice isoforms, conserved between mouse and man. Individual isoforms are characterized by presence of either one of two types of long C-termini (tail versions 1 or 2; DMPK isoforms A to D) or a rather short C-terminus (tail 3; isoforms E and F), combined with absence or presence of an internal VSGGG-motif (A vs B, C vs D, E vs F) [5]. DMPK isoforms A–D are typical tail-anchored proteins with a membrane segment in their C-terminus. These isoforms are mainly expressed in heart, skeletal muscle and brain. Isoforms E and F are cytosolic proteins, predominantly found in smooth muscle cells [2,5,8].

Previously, we demonstrated that tail anchors in DMPK A/B and DMPK C/D drive binding to specific organellar membranes [9]. In mouse, this results in binding of mDMPK A and B to the endoplasmic reticulum (ER) and in binding of mDMPK C (and D) to the mitochondrial outer membrane (MOM). In humans, hDMPK A/B and C/D have also distinct tails, but these isoforms all anchor to the MOM. Isoform hDMPK A is unique in that its transient expression causes mitochondrial morphology to become abnormal, eventually leading to cell death via an as yet unidentified mechanism [10].

Mitochondria form an elaborate network with variable morphology and spatial distribution, tightly controlled by the physiological state of the cell and dependent on cell type and metabolic needs [11]. Organellar form and function in this...
network are regulated by fission and fusion with important bearing on the internal distribution of energy metabolites, the mode of sequestration of intracellular Ca\(^{2+}\) ions [12] and perhaps even apoptosis signaling [13]. MOM-associated proteins like mitofusins 1 and 2 (Mfn1 and 2) and OPA1 or hFis control mitochondrial fragmentation or perinuclear localization [14–17].

Various diseases, either coupled to acquired or inherited defects in bioenergetic circuits or to abnormalities in the fusion-fission machinery have been associated with abnormal mitophyiology [18]. Also in DM1 patients, abnormal mitochondrial form and mitochondrial dysfunction have been described [19,20]. Furthermore, overexpression of RNA and protein products from a hDMPK (CTG)\(_{11}\) transgene in a DM1 mouse model induced accumulation of mitochondria in the subsarcolemmal space and formation of aberrant cristae and caused a reduced workload tolerance in mice [21].

Quantitative and qualitative aspects of DMPK biology—via mitochondrial involvement—could thus contribute to typical features of DM1 disease manifestation, including defective Ca\(^{2+}\) ion homeostasis, insulin resistance and loss of cell viability in muscle, brain and other organs [7]. Here we report on one aspect, consequences of expression of the hDMPK A isoform, in particular its binding to the MOM. By use of transfection-complementation experiments in cultured cells, with or without DMPK deficiency, we analyze hDMPK A’s role in determining mitochondrial fate and function and the functional integrity of the cell. We demonstrate that the protein’s C-terminal tail is sufficient for induction of perinuclear clustering. Microscopy and biochemical analysis revealed that mitochondrial clustering was associated with increased autophagic activity. Ultimately, decoration of mitochondria with hDMPK A results in loss of cell-functional integrity and in the initiation of apoptosis.

### Results

The tail region of hDMPK A is responsible for perinuclear mitochondrial clustering

Earlier, we had observed that hDMPK A has the capacity to localize to the MOM and affect mitochondrial distribution in a broad range of cell lines [10]. To analyze quantitative and qualitative aspects of this phenomenon in more detail, we used transfection of C\(_2\)C\(_1\)2 myoblasts, a natural host cell line for DMPK proteins [8]. Transfection of YFP-hDMPK A resulted in mitochondrial decoration in \(\sim60\%\) of all YFP-positive cells, while for the remaining \(\sim40\%\) a cytosolic fluorescence without mitochondrial binding was observed. In contrast, mitochondrial YFP-fluorescence was found in virtually all cells that expressed YFP-hDMPK C. Classification of cells with MOM-bound YFP-hDMPK A (see Figure 1A for morphological classes) revealed that the majority of cells contained mitochondria with a clustered appearance (Figure 1B). Approximately 25% possessed fragmented mitochondria and only few showed a network of normal, elongated mitochondria. Frequencies in the different categories varied somewhat with experimental conditions, including transfection dose and duration (data not shown). Virtually all mitochondria in cells with cytosolic YFP-hDMPK A displayed a normal elongated appearance (Figure 1A, lowest panel), similar to cells with MOM-bound YFP-hDMPK C or mock-transfected cells. Taken together, these observations suggest that mitomorphological changes are only induced in cells where hDMPK A proteins are associated to mitochondria.

To investigate whether the entire protein or only domains of hDMPK A are involved in this phenomenon, a series of YFP-fusion constructs was designed (Figure 1C) and expressed in C\(_2\)C\(_1\)2 myoblasts (Figure 1D). Tagging with monomeric L221K YFP variant was incorporated to exclude involvement of the dimerizing capacity of the YFP portion [9]. Use of this monomeric YFP tag did not affect hDMPK A’s mitochondrial clustering behavior, demonstrating that this is indeed an intrinsic property of the DMPK moiety itself (Figure 1D). Importantly, mitochondrial clustering was still observed when the kinase-dead K100A mutant was expressed (Figure 1D), consistent with the idea that enzymatic activity is not required. Since hDMPK C also anchors at mitochondria but does not change mitochondrial morphology, even though it differs from hDMPK A only in the C terminus [10], we hypothesized that the tail domain must be responsible for mitochondrial clustering. Indeed, expression of mutant YFP-hDMPK A\(_{534–629}\) confirmed that clustering capacity was entirely contained within hDMPK A’s C-terminus (Figure 1D).

It is well known that the 3’ UTR of a mRNA can determine gene product distribution and function in cells [22]. The 3’ UTR of hDMPK mRNA, when overexpressed, has been shown to be detrimental to cardiomyocytes and myofibers [23]. We therefore verified whether mitochondrial behavior differed between situations where hDMPK A protein was expressed from constructs with or without its normal 3’ UTR (Figure 1C and 1E), but found no differences. Also, a control vector containing a YFP ORF followed by the DMPK 3’ UTR gave the anticipated cytosolic and nuclear YFP distribution. Thus, our data indicate that the 3’ UTR is not involved in hDMPK A-induced mitochondrial clustering.

In most cell types where the DMPK gene is naturally expressed, isoforms A and C are present in approximately equal amounts [5,8, Mulders and Wansink, data not shown]. To test whether presence of hDMPK C could prevent hDMPK A from inducing mitochondrial clustering, we used N2A cells, well known for their high transfection efficiency, to generate sufficient numbers of cells that coexpressed hDMPK A and C in a double transfection. Isoform hDMPK C failed to modulate formation of mitochondrial clusters in all doubly transfected cells, indicating that hDMPK A effects are dominant (Figure 1F).

Microtubule depolymerization reduces mitochondrial clustering

The cytoskeleton controls interactions in the mitochondrial network, facilitated by a host of membrane fission/fusion proteins, motor and adaptor proteins. Mitochondria are transported along microtubules and actin microfilaments [24]. Since hDMPK A appears to affect mitochondrial dynamics and is also believed to affect actomyosin behavior [6,7], we reasoned that its role could be at the cytoskeletal-mitochondrial interface.

Comparison of the actin and microtubule cytoskeletons in cells with YFP-hDMPK A or C expression did not reveal any overt effect on structural integrity (Figure 2A and 2B). We also examined what the absence of tubulin or actin filaments would do to the perinuclear accumulation of mitochondria [25,26]. DMPK KO mouse myoblasts [10] were reconstituted with hDMPK A or C isoforms by adenoviral transduction and immediately treated with cytochalasin D or nocodazole. F-actin depolymerization-disorganization by cytochalasin D did not alter clustered mitochondrial morphology as revealed by comparison between YFP-hDMPK decoration patterns in A and C isoform-transfected cells (Figure 2A). Also the frequency of clustering was not altered by cytochalasin D treatment (measured as the percentage of transfected cells that displayed clustered mitochondria; Figure 2C). In contrast, in cells with nocodazole-induced microtubular disorganization, the fraction of hDMPK A-expressing cells displaying perinuclear accumulation of mitochondria was significantly reduced, even though the fragmented appearance of
Figure 1. Perinuclear clustering of mitochondria is induced by the C-terminal domain of hDMPK A. (A,B) C2C12 myoblasts transiently expressing YFP-hDMPK A or C fusion proteins or mock-transfected cells were stained with a cytochrome c oxidase antibody to visualize mitochondria. Typical examples of classes of mitochondrial morphology are shown in (A). Mitochondrial distribution was classified as fragmented, clustered or elongated. Frequencies of appearance are listed as percentage of the total number of cells expressing MOM-associated hDMPK A (n = 3, ~50 cells analyzed per experiment). Around 40% of YFP-hDMPK A-expressing cells showed a cytosolic expression. These cells contained mitochondria with a typically elongated shape, but were disregarded in the analysis. (C) Schematic representation of YFP constructs used for transfection expression with protein domains, mutations and 3' UTR indicated. (D) C2C12 myoblasts expressing YFP fusion proteins were stained with a cytochrome c oxidase antibody to visualize their ability to induce clustering of mitochondria. (E) Expression of constructs with altered 3' UTRs demonstrated that the hDMPK A 3' UTR was not involved in mitochondrial clustering. (F) Co-expression of YFP-hDMPK A and hDMPK C-HA in N2A cells resulted in mitochondrial clustering, whereas cells only expressing hDMPK C-HA exhibited normal, elongated mitochondria. Bars, 10 μm.
doi:10.1371/journal.pone.0008024.g001
the mitochondrial network remained (Figure 2B and 2C). When nocodazole was washed out at 12–16 hours after transduction and expression was continued for an additional 8 hours, the percentage of cells with mito-clusters was significantly higher than among cells that were continuously treated with nocodazole (Figure 2D).

Nocodazole had no overt effect on mitochondrial location or morphology in hDMPK C-expressing cells. To us, these observations suggest that hDMPK A-induced fragmentation and clustering are at least partly uncoupled effects and that microtubular infrastructure only affects the extent of clustering.

Figure 2. An intact microtubular cytoskeleton enhances hDMPK A–induced perinuclear mitochondrial clustering. DMPK KO myoblasts were transduced with YFP-hDMPK A or C-expressing adenoviruses in the presence of cytochalasin D (A) or nocodazole (B). F-actin was visualized by fluorescent phalloidin. The microtubular cytoskeleton was stained with an anti-tubulin antibody. Disruption of the actin cytoskeleton did not affect localization of mitochondria. Depolymerization of microtubules decreased mitochondrial clustering in YFP-hDMPK A-expressing cells, but mitochondria still appeared fragmented. The distribution of mitochondria in YFP-hDMPK C-transduced cells was unaffected by nocodazole treatment. Bars, 10 μm. (C) Quantification of mitochondrial clustering. The number of transduced cells that contain clustered mitochondria are expressed as percentage of the total amount of cells expressing hDMPK A at the MOM, with or without treatment of cytochalasin D or nocodazole (images shown in A and B; n = 3, ~100 cells per experiment, P = 0.01). (D) Effect of nocodazole wash-out. Quantification of the percentage transduced cells with clustered mitochondria after a 12–16 hours treatment with nocodazole, followed by a 8 hours wash-out (n = 3, ~30 cells per experiment, P<0.05).

doi:10.1371/journal.pone.0008024.g002

Mitochondrial morphology changes soon after hDMPK A translocation

To obtain insight in spatio-temporal aspects of mitochondrial morphology alterations, KO myoblasts were transduced with YFP-hDMPK isoforms and subjected to live imaging. Mitochondria were visualized via MitoTracker Red staining and images were taken every three minutes. YFP-hDMPK A located in the cytosol at first appearance, but translocated and concentrated at the MOM within four hours, after which fragmentation and clustering of mitochondria occurred (Figure 3A). YFP-hDMPK C...
appeared directly on mitochondria without inducing mitochon-
drial clusters (Figure 3B). In transfected N2A cells, initial YFP-
hDMPK A staining in the cytosol was less evident and hDMPK A
appeared at the MOM without intermediate accumulation,
directly after expression onset. Size changes and clustering of
mitochondria could be detected as early as six hours after
transfection in these cells (Figure 3C). Combining these data with
findings in other cell lines [10] demonstrates that timing of
expression and sorting of DMPK isoforms may differ between cell
types, but the sequence of events that is induced once DMPK A is
associated with mitochondria is qualitatively similar.

Abnormal mitochondrial ultrastructure develops upon
hDMPK A expression

We performed electron microscopy (EM) on N2A cells
expressing hDMPK A to investigate effects on mitochondrial
ultrastructure and cell architecture. YFP-hDMPK A-transfected
cells were easy recognizable by the concentration of mitochondria
in the juxtapluclear region (Figure 4A), while other parts of the cell
were left completely void of mitochondria (Figure 4B). Clustered
mitochondria showed a rounded morphology, often with disorga-
nized or absent cristae structure and a decrease of electron density
in the matrix (Figure 4A). Cells with this appearance were never
seen in YFP-hDMPK C-transfected cultures. In control cells or
cells expressing YFP-hDMPK C mitochondria contained a
normal, intact cristae structure, were more elongated and had a
disperse localization (Figure 4C).

Besides abnormal mitochondria, we identified an increased
number of autophagic structures after hDMPK A expression
(Figure 4A). These autophagosomes varied in size and were found
near and within areas of clustered mitochondria. In some cases,
mitochondrial remnants could still be recognized, indicative of
mitophagy. The fraction of cells containing autophagic structures
was assessed by LM and EM and amounted to 12–14% after YFP-
hDMPK A expression and 5–6% in cells with YFP-hDMPK C.

As a second indicator of autophagy, we measured conversion of
LC3b protein using western blotting [27]. In transduced myoblasts
significant conversion to the LC3b-II form was observed after 16–
24 hours of expression of YFP-hDMPK A, but not C (Figure 4D).
These observations were confirmed in N2A cells (data not shown).
On blot, we repeatedly observed a reduced hDMPK A level within
the 16–24 h period of expression. We attribute this finding to a
selective loss of cells with highest DMPK A expression (see below).
Although this may have influenced our picture of kinetics of
autophagy induction in the entire pool of cells, our data
collectively point to a gradual viability loss in the majority of cells
in the transfected pool.

Clustering of mitochondria results in loss of function

Against this background, knowing that mitochondrial integrity
and function are dynamically linked and tightly coupled to the
cell’s physiological state [11,28], we investigated hDMPK A effects
on cell viability further. To force utilization of relevant metabolic
energy pathways, C2C12 myoblasts were kept in media of different
composition, including high or low oxygen supply, and monitored
after transfection with YFP-hDMPK A or C. Cell survival was
similar for YFP-hDMPK A-expressing cells growing under normal
conditions or high glucose conditions with low oxygen plus use of
mitochondrial uncoupler FCCP (to maximally prevent mitochon-
drial OXPHOS activity; Figure 5A). This outcome can be
explained because normal growth of cells in culture already
strongly relies on glycolytic metabolism [29] and therefore cannot
be further promoted. In glucose-deprived medium supplemented
with galactose, forcing cells to rely on mitochondrial oxidative
phosphorylation [30], hardly any YFP-hDMPK A-expressing cell
survived (Figure 5A). This suggests that clustering of mitochondria
is detrimental for cell viability, especially in aerobically-poised
situations when cells are forced to use mitochondrial TCA/
OXPHOS activity. As a control, YFP-hDMPK C-expressing cells

Figure 3. Mitochondrial clustering is a rapid process and occurs already at low hDMPK A expression. KO myoblasts were
transduced with YFP-hDMPK fusion proteins (top panels), while mitochondria stained with MitoTracker Red (bottom panels). Images
were collected every three minutes. The time of first appearance of YFP signal was set at t = 0; other time points are indicated in the top panels.
(A) YFP-hDMPK A was first detected in the cytoplasm. Soon YFP-
hDMPK–decorated mitochondria appeared which then started to
cluster, eventually resulting in severely aggregated mitochondria
surrounding the nucleus. (B) YFP-hDMPK C directly appeared on
mitochondria which maintained their elongated, reticular structure. (C) In N2A cells, YFP-hDMPK A expression emerged in a similar fashion as in
KO myoblasts, except that mitochondrial clustering occurred almost
immediately and cytosolic staining was less pronounced.
doi:10.1371/journal.pone.0008024.g003
showed no differences in cell survival under these culture conditions (Figure 5A).

Formation of an electrochemical proton gradient across the inner mitochondrial membrane drives ATP production by OXPHOS [31]. To compare possible effects of DMPK isoforms on this coupling, we used staining of YFP-hDMPK A and C-expressing HeLa cells with the fluorescent dye TMRM, which provides a readout for the mitochondrial membrane potential (MMP). HeLa cells were chosen because these have been used before for MMP determination and gave sufficient TMRM signal strength for quantitative analysis [32]. Before measurement, depolarization with FCCP as described by Distelmaier et al. [33] was used to control that TMRM accumulation did not involve quenching, becoming a confounding factor in MMP measurement. For many other cell lines the 100 nM TMRM concentration appeared toxic or TMRM did not accumulate well enough in mitochondria to generate adequate signals (data not shown). YFP-hDMPK A-expressing HeLa cells showed a significantly lower MMP than cells that expressed YFP-hDMPK C (Figure 5B and 5C). Interestingly, YFP-hDMPK A-positive cells with no or only mild mitochondrial clustering showed a normal MMP (Figure 5B, upper panels). The lack of signal in clustered mitochondria could not be due to an inability to take up TMRM, since they were able to internalize the related compound MitoTracker Red (data not shown). The MMP in YFP-hDMPK C-expressing cells was not significantly different from that in untransfected cells (Figure 5C).

Cells with clustered mitochondria undergo apoptosis

We observed that YFP-hDMPK A-expressing KO myoblasts - but not YFP-hDMPK C expressing cells - died rapidly after prolonged periods of transfection-complementation and wondered whether this loss could be explained by an apoptosis-based mechanism. One finding supporting this conjecture was that treatment with apoptosis inhibitor z-vad-fmk immediately after transfection significantly increased the number of surviving hDMPK A-expressing cells, whereas no effect was seen on the viability of cells expressing hDMPK C (Figure 6A). Further support was obtained by the observation that little or no staining of cytochrome c, a mitochondrial intermembrane protein, was present in clustered mitochondria in YFP-hDMPK A-expressing KO myoblasts (Figure 6B, upper panels), while mitochondria that were only fragmented did contain cytochrome c (Figure 6B, middle panels). To us this suggests that release of cytochrome c, a well known apoptosis-triggering event [34], probably occurs after the onset of mitochondrial clustering. No cytochrome c release was observed for YFP-hDMPK C-expressing cells (Figure 6B, lower panels).

Figure 4. Mitochondrial clustering is accompanied by aberrant ultrastructural morphology. N2A cells were transfected with YFP-hDMPK A or C isoforms and ultrastructure was analyzed by electron microscopy. (A) YFP-hDMPK A–expressing cells contained fragmented, clustered mitochondria near the nucleus. Cristae structure was often lost together with electron density of the matrix (arrowhead) and mitophagy was observed (arrow). In contrast, other areas of the cell were completely devoid of mitochondria (B). (C) Mitochondrial morphology was normal in hDMPK C–expressing cells. A fragment of the nucleus is included here for orientation. Note the proper cristae structure and loose distribution of mitochondria and endoplasmic reticulum. Bars, 1 μm. (D) Lysates from myoblasts expressing YFP-hDMPK A or C for 8, 16 or 24 hours were used for western blotting with a LC3b antibody and showed an increased LC3b conversion following YFP-hDMPK A expression. Cells cultured under normal conditions and nutrient-starved cells, cultured in Earle’s Balanced Salt Solution (EBSS) for 2 hours, were used as negative and positive controls, respectively. DMPK expression was verified using a DMPK antibody. Tubulin (T) antibody staining was used as loading control.

doi:10.1371/journal.pone.0008024.g004
Discussion

We demonstrate here that expression of MOM-anchored hDMPK A results in fragmentation of the mitochondrial network and perinuclear clustering of morphologically-altered mitochondria. In addition to these morpho-mechanical changes, physiological changes like loss of MMP, increased autophagosomal activity and leakage of cytochrome c accompanied by apoptosis were induced. It is difficult to bring hierarchical ordering in these events, but we propose that the fate of mitochondria in cells with hDMPK A is specified as follows: based on our observations with live-cell imaging and the finding that microtubule disruption attenuated clustering, we suppose that induction of morphological change is the initiating step that marks mitochondria for subsequent anomalous transport and clustering. Upregulation of autophagy may be an intermediate phase to rescue defective energy and clear mitochondrial waste [35].

The fact that the same sequence of events in mitochondrial fragmentation and perinuclear clustering with globally similar final outcome occurred in all mouse and human cell types examined is important. Slight variation in the speed and magnitude of events was observed between cell types, but this can most easily be explained by differences in cytoarchitectural arrangement, pathophysiological thresholds or stress-coping ability. Toxicity of hDMPK A was also observed in KO myoblasts in which DMPK was reconstituted to apparently normal expression levels by complementation. We observed mitochondrial clustering already after several hours of hDMPK A expression when ectopic protein levels were still relatively moderate. Therefore, we postulate that induction of abnormal mitochondrial behavior is an intrinsic capacity of hDMPK A and cannot be simply explained as a result of overexpression. Mutational analysis demonstrated that hDMPK A’s tail region was sufficient to induce mitochondrial fragmentation and clustering. The conclusion that this is the only segment with detrimental effects was corroborated by the observation that MOM-binding of hDMPK C, which differs from hDMPK A only in its C-terminus, had no effect on mitochondrial physiology and trafficking.
Figure 6. Expression of hDMPK A induces apoptosis. (A) The effect of apoptosis-inhibitor z-vad-fmk was tested on cell survival of DMPK KO myoblasts transduced with YFP-hDMPK A or C-expressing adenoviruses. YFP-positive cells were counted after 16, 24, and 48 hours. Z-vad-fmk greatly reduced cell death of YFP-hDMPK A–expressing cells, but had no effect when YFP-hDMPK C was expressed. Z-vad-fmk was applied immediately after transduction and maintained present for the remaining time of the experiment. Values at 16 hours were set at 100% (P<0.05, n = 3, >90 cells counted per experiment). (B) YFP-hDMPK A and C–expressing cells were stained for cytochrome c (cyt c). Cells expressing YFP-hDMPK A displayed a diffuse, cytosolic cytochrome c staining when mitochondria were clustered (upper panels). A clear mitochondrial staining was present when mitochondria appeared fragmented (middle panels). A discrete, mitochondrial cytochrome c staining was also observed in YFP-hDMPK C–expressing cells. Bars, 10 μm.

doi:10.1371/journal.pone.0008024.g006

Interesting parallels can be drawn to the morphophysiological effects induced by ectopic or overexpression of other MOM proteins, like TA proteins hFis [15,36], Miro GTPases [37,38] and Mfn 1 and 2 proteins [14,17,39]. All these enzymes are involved in mitochondrial dynamics. Although similar in nature, changes evoked by these MOM proteins cannot be simply lumped together, since it is unclear how mitochondrial clustering occurs, and clear mechanistic differences can be noted. For example, enzymatic activity appears irrelevant for Mfn 1 and 2 [14,17,39] and hDMPK A (this paper), but is necessary for hFis [36] and Miro 1 and 2 [37]. We demonstrate that hDMPK A effects do not require coiled-coil interactions between proteins, but Mfn 1 and 2 effects clearly rely on these associations [40]. The status of the cytoskeleton does not determine Mfn 2 effects [14], yet hDMPK A clustering partly depends on integrity of microtubules. It is tempting to speculate that every distinct TA-containing MOM protein has its own role in creating an appropriate microenvironment for mitochondrial interactions with other cell structures. Reactions mediated by these proteins may involve distinct areas in the MOM and also the complex and diverse machinery that links mitochondria to motor proteins may be differentially involved [37,38,41,42]. Disbalance in any of these systems may create overtly similar effects, with fragmentation and clustering of mitochondria as main outcome.

Mitochondrial fragmentation and clustering is probably an intrinsic property of the hDMPK A membrane anchor itself. There is mounting evidence indicating that certain hydrophobic regions in membrane proteins are able to induce membrane curvature and remodeling. Our EM data demonstrate that hDMPK A-decorated mitochondria are small and round - i.e., not one large continuum - suggesting that lipid-protein or lipid-lipid interactions become abnormally affected in presence of the tail anchor of hDMPK A. Direct effects of membrane anchors that result in distortion of protein-protein interaction and clustering followed by formation of abnormal membrane curvature, vesicle formation or fragmentation have been described [43,44]. Coupling to abnormal fusogenic properties of hDMPK A's anchor could also be involved. It has been shown that Leu/Val residues and Gly/Pro or Pro/Gly pairs in peptides in transmembrane domains add to a high fusogenic index [45,46]. Exactly these amino acids are highly abundant in the tail region of hDMPK A. Recent studies have shown that the physiological state of mitochondria is reciprocally coupled to morphological appearance [17,47]. Recently, even a relationship between mitochondrial form and cell cycle control has been reported [48]. Although mitochondrial fragmentation has been observed frequently in cells undergoing apoptosis, its active role in apoptosis is still unclear [36,49]. We observed that hDMPK A-induced morphological effects ultimately lead to cell death and provide evidence that cytochrome c leak did not occur and MMP was still largely intact in hDMPK A-decorated mitochondria that were still in the fragmented state. Loss of cytochrome c and disappearance of MMP was observed when mitochondria became cluster. We take these observations to indicate that events that occur during or just before mitochondrial clustering must contribute to the onset of apoptosis.

Aberrant mitochondrial morphology is linked to multiple disease manifestations caused by mutations in genes involved in fission and fusion, like Charcot-Marie-Tooth subtype 2A and dominant optic atrophy [18,28]. Also in DMI patient muscle, mitochondrial irregularities have been found, although the cause of these malformations has not yet been identified [19,20]. Studies involving
on Tg26-\textit{hDMPK} mice, overexpressing tail-anchored hDMPK isoforms especially in heart and skeletal muscle, showed disorganized cristae structure and symptoms like reduced workload tolerance, atriopt, hypertrophic cardiomyopathy, myotonic myopathy and hypotension, reminiscent of DM1 symptoms [21].

We do not expect that the normal physiological function of hDMPK is directly related to regulation of mitochondrial clustering. Like hDMPK C, hDMPK A is predominantly expressed in skeletal muscle myofibers [5,6], a cell type with a rigidly compartmentalized cytoarchitectural infrastructure and well-defined mitochondrial distribution across intramyofibrillar and subsarcomemal areas. This typical robust cytoarchitectural organization may render muscle cells more resistant to fluctuations in \textit{hDMPK} A expression, but based on our findings we speculate that also for myotubes it is of paramount importance that hDMPK A protein levels are tightly regulated and strictly kept within the normal physiological range. Expression levels of completely other proteins, for example VEGF, also require tight regulation as both reduced and increased expression can result in pathogenesis, manifesting itself in embryonic lethality or cancer, respectively [50]. Changes in DMPK mRNA synthesis or pre-mRNA splicing induced by the presence of expanded (CUG)n transcripts, when resulting in only a slight disbalance in \textit{hDMPK} A expression level, could thus be a contributing factor in the pathophysiology of DM and explain mitochondrial abnormalities. In more extreme situations like congenital DM with very large (CTG)n expansions, where abnormal chromatin modification and defective bidirectional transcriptional control across the DM locus may directly couple to unbalanced DMPK production, the toxic effects of DMPK A may even directly contribute to special disease features [51,52]. Further research into the role of hDMPK A in health and disease is thus warranted and also needed to validate this model and its predictions. A more precise study of the balance in DMPK splice isoforms in different categories of DM1 patients is a necessary first step.

**Materials and Methods**

**Antibodies and chemicals**

Staining with anti-cytochrome c oxidase antibody [53] was used to visualize mitochondria and monitor apoptosis. Monoclonal β-tubulin antibody E7 (Developmental Studies Hybridoma Bank, University of Iowa, Iowa City, Iowa) was used to stain the tubulin cytoskeleton. TexasRed-conjugated-phalloidin staining (Molecular Probes, Breda, The Netherlands) was used to visualize F-actin. Probes, Breda, The Netherlands) was used to visualize F-actin. Cytochalasin D (Sigma) was used to detect the HA epitope tag. For western blotting, DMPK-cytochalasin D (Sigma). Mouse monoclonal antibody 12CA5 was used. Polyclonal antibody (Cell Signalling, Beverly, Massachusetts) were used. HeLa cells were maintained at 37°C under a 5% CO2 atmosphere. To maximally stimulate glycolytic metabolism, C2C12 myoblasts were cultured in DMEM, 10% FCS with 1 mM sodium pyruvate, 2 mM glutamine and 10% dialyzed FCS. Cells were maintained at 37°C under a 5% CO2 atmosphere. To maximally stimulate glycolytic metabolism, C2C12 myoblasts were cultured in DMEM, 10% FCS with 1 mM glucose and 1 μM of the mitochondrial uncoupler FCCP (Sigma, Zwijndrecht, The Netherlands) and maintained at 37°C under a 2% O2 atmosphere. Cells were allowed to adapt to these culture conditions for 5 days, transfected with equal amounts of plasmid DNA encoding YFP-hDMPK A or C and then maintained in culture for an additional 20 hours before the number of YFP-positive cells was analyzed.

Autophagy was induced by placing cells in nutrient-starvation medium Earle’s Balanced Salt Solution (EBSS) for two hours.

**Plasmids and adenoviral vectors for DMPK expression**

EYFP-DMPK expression vectors were obtained by cloning appropriate DMPK cDNA segments into pEYFP-C1 (Clontech, Saint-Germain-en-Laye France) and pSG8AEC vectors [2,10]. Inserts of all expression plasmids were composed of relevant domains from the open reading frames plus the adjacent 3′ UTR of DMPK cDNAs. All segments obtained via PCR were verified by DNA sequencing.

**MonoYFP-hDMPK A**

To introduce a L221K mutation into YFP, pEYFP-C1 vector was PCR-amplified with forward primer 5′-GATCAGATGGTCCTTTAAAGGATGTCTGACC-3′ and reverse primer 5′-GGTCAGAAACTCCTTTAGGGACCATGTTGATC-3′ (mutation underlined). The resulting fragment was digested with BsrGI and NotI, gel purified and subcloned into pEYFP-C1. A BglII excised hDMPK A fragment was introduced into the BglII site.

**YFP-hDMPK A**

A PCR fragment was amplified by site-directed mutageneis as a template pEYFP-hDMPK A plasmid with forward primer 5′-GGCCAGGTGGTATGGCGATGCCAATCTGAAAGGGTGGGAC-3′ and reverse primer 5′-GTCACAGGACCTCCTTTAAAGGACCATGTTGATC-3′ (mutation underlined). The resulting fragment was digested with BglII and NotI, gel purified and subcloned into pEYFP-C1. A BglII excised hDMPK A fragment was introduced into the BglII site.

**YFP-hDMPK A**

A fragment encompassing human tail 1 including the 3′ UTR was PCR-amplified from pEYFP-hDMPK A with forward primer 5′-GGGAAGATCTGTGTCACGGGGGTCC-3′ adding a BglII site (underlined) and reverse primer 5′-TGCAATTCATTGAGGACCATGGAACAGCAAC-3′ located in the multiple cloning site of the pEYFP-C1 backbone. The resulting DNA was trimmed with BglII, gel purified and subcloned into the polylinker of vector pEYFP-C1.

**YFP-hDMPK A**

A fragment encompassing human tail 1 excluding the 3′ UTR was PCR-amplified from pEYFP-hDMPK A with forward primer 5′-GGGAAGATCTGTGTCACGGGGGTCC-3′ adding a BglII site (underlined) and reverse primer 5′-GCAATTCATTGAGGACCATGGAACAGCAAC-3′ located in the stop codon containing an EcoRI site (underlined). The resulting DNA was trimmed with BglII and EcoRI, gel purified and subcloned between two BglII sites of pEYFP-hDMPK A.
YFP-3' UTR. A fragment encompassing the hDMPK A 3' UTR was PCR-amplified from pEYFP-hDMPK A, with forward primer 5'-GGAAAGATCTTGGACCTAGAAGCTTGTTCC-3' adding a BgII site (underlined) and reverse primer 5'-GGCAATTACAGTCAATCTC-3' located in the multiple cloning site of pEYFP-C1 backbone. The resulting PCR product was digested with BgII, gel purified and subcloned into the polylinker in vector pEYFP-C1.

hDMPK C-HA. A fragment encompassing the final 900 bp of the coding region of hDMPK C was amplified by PCR from pEYFP-hDMPK C with forward primer 5'-GGCCGCTTACCTTAGGGTTATCTGGAATACAGTCAATCTC-3' and reverse primer 5'-GGCAATTACAGTCAATCTC-3' located in the multiple cloning site of pEYFP-C1. The PCR product was digested with SacI and SalI resulting in a 800 bp fragment. A fragment of about 1.1 kb encompassing the 3' UTR of hDMPK C was PCR amplified with forward primer 5'-GGCCGCTTACCTTAGGGTTATCTGGAATACAGTCAATCTC-3' adding a KpnI site (underlined) and reverse primer 5'-GGCAATTACAGTCAATCTC-3' located in the multiple cloning site of pEYFP-C1. The PCR product was digested with KpnI and SalI and subcloned into pShuttle-CMV. In a second step, KpnI and SalI sites were created by adding a BglII site (underlined) and reverse primer 5'-GGCAATTACAGTCAATCTC-3' located in the multiple cloning site of pEYFP-C1.

 Luciferase assay. Cells were seeded in 24-well plates at 3-5 x 10^4 cells per well 24 h prior to transfection. Transfections were performed using 1 μl of Lipofectamine 2000 (Invitrogen) per well in 100 μl of Opti-MEM (Invitrogen). After 4-6 h of transfection, the medium was replaced with fresh medium and cells were cultured for an additional 20 h. At the end of the incubation period, the medium was aspirated and 100 μl of lysis buffer (25 mM Tris-HCl, pH 7.5, 250 mM NaCl, 1 mM EDTA, 0.5% Nonidet P-40 and 1% Triton X-100) was added to each well. The plates were incubated for 1 h at 4°C and the lysates were harvested. Luciferase activity was measured with a dual luciferase reporter assay system (Promega) according to the manufacturer's instructions.

Western blotting.

 Cell lysates were separated by SDS-PAGE and transferred onto nitrocellulose membranes. The membranes were blocked with 5% nonfat dry milk in TBS-T for 1 h at room temperature and then incubated overnight at 4°C with the primary antibody. After washing, the membranes were incubated with the secondary antibody conjugated to HRP. Immune complexes were visualized by chemiluminescence using a chemiluminescence detection system (Amersham Biosciences). The intensity of the bands was quantified using the ImageJ software (National Institutes of Health).

Mitochondrial membrane potential (MMP)

HeLa cells were cultured in media containing 10% fetal bovine serum (FBS) and 2 mM glutathione. After reaching 80% confluence, cells were transfected with pEYFP-hDMPK A and pEYFP-hDMPK C. After ~20 h, cells were stained for 30 minutes using 1 μM TMRM (Invitrogen) in DMEM supplemented with 10% FCS. TMRM fluorescence was measured using a confocal microscope. TMRM fluorescence was measured at 555 nm with an acquisition/illumination time of 100 ms using a monochromatic emission filter (Omega) at 565 nm. No bleed-through was detected. All imaging was performed using a spinning disk confocal microscope (LaserSharp2000, Andor Technology). Hardware was controlled by and images were analyzed using Metamorph 6.2 software for mean fluorescence intensity of the mitochondrial area.

Electron microscopy

Cells were fixed and embedded as described for EM analysis. Endosomes and lysosomes were observed using a transmission electron microscope (Philips CM120, FEI). Images were acquired using a Gatan Ultrascan 1000 digital camera and processed using Digital Micrograph software (Gatan, Inc.). The thickness of the endosomal and lysosomal membranes was measured using ImageJ software.

Autophagosome quantification by LM and EM

Samples were fixed and embedded as described for EM analysis. 1% osmium tetroxide was included to increase visibility of membranes [59]. Sections of 0.5 μm were cut and stained with toluidine blue. Sections were mounted on a cover glass using...
Eukitt (Sigma-Aldrich) and analyzed using light microscopy with a Leica DM6000B/CTR6000 imaging system and Leica IM500 Image Manager acquisition software (Leica, Solms, Germany). The percentage of cells containing one or more spheroid autophagosome structures was quantified. Quantification on ultrathin sections by electron microscopy was done in a similar manner.

**Statistics**

Data are expressed as mean ± s.e.m. Between group comparison was performed by two-tailed unpaired Student’s t-test. Differences between groups were considered significant when P<0.05, * P<0.05, ** P<0.01, *** P<0.001. Statistical analyses were performed with GraphPad Prism 4 software. The number of replicates and the number of cells counted per experiment are described in the figure legends.

**Acknowledgments**

We thank Werner Koopman (Department of Biochemistry, NCMLS, Radboud University Nijmegen Medical Centre) for discussions and helpful advice.

**Author Contributions**

Conceived and designed the experiments: RJAOO JAMF BW DGW. Performed the experiments: RJAOO MW MBB. Analyzed the data: RJAOO MW JAMF BW DGW. Contributed reagents/materials/analysis tools: FAvdL. Wrote the paper: RJAOO BW DGW.
