SUMMARY

Mucocutaneous fungal infections are typically found in patients who have no known immune defects. We describe a family in which four women who were affected by either recurrent vulvovaginal candidiasis or onychomycosis had the early-stop-codon mutation Tyr238X in the β-glucan receptor dectin-1. The mutated form of dectin-1 was poorly expressed, did not mediate β-glucan binding, and led to defective production of cytokines (interleukin-17, tumor necrosis factor, and interleukin-6) after stimulation with β-glucan or *Candida albicans*. In contrast, fungal phagocytosis and fungal killing were normal in the patients, explaining why dectin-1 deficiency was not associated with invasive fungal infections and highlighting the specific role of dectin-1 in human mucosal antifungal defense.

R E C U R R E N T V U L V O V A G I N A L C A N D I D A S I S I S A R E L A T I O N L Y C O M M O N pathological condition, afflicting women of all ages, with more than 90% of cases caused by *C. albicans*. Although the role of diabetes as a predisposing condition has been recognized, most cases occur in healthy women. Recurrent oral, esophageal, or mucocutaneous candidiasis is also diagnosed in some patients without clear predisposing factors. Onychomycosis is a common infection of the nail beds, most often caused by dermatophytes but sometimes caused by *C. albicans*, that also affects immunocompetent persons. In contrast, disseminated forms of candida infections are mostly found in patients in whom a defect in neutrophil function is easily recognized or candida species have been introduced in the bloodstream through invasive procedures. Very little is known about the genetic factors predisposing patients to mucosal or disseminated candida infections.

Recognition of *C. albicans* by the innate host defense system is mediated by pattern-recognition receptors from the toll-like–receptor (TLR) and lectinlike-receptor families. Mannans from the candida cell wall are recognized by the mannose receptor and TLR4, and TLR2 recognizes phospholipomannan and collaborates with the β-glucan receptor dectin-1 in the stimulation of cytokine production.7,8

Recognition of 1,3-linked β-glucans by dectin-1 has been shown to be one of the main fungal-recognition pathways, and mice deficient in dectin-1 have an increased susceptibility to C. albicans and Pneumocystis carinii. Dectin-1 amplifies TLR2- and TLR4-induced cytokine production in both murine and human cells, resulting in the production of cytokines such as tumor necrosis factor, but also induces signals, independently of the TLRs, for the production of interleukin-17, interleukin-6, and interleukin-10 through a pathway dependent on spleen tyrosine kinase.

GENETIC ANALYSIS
A detailed description of the methods used to sequence the dectin-1 gene is presented in the Supplemental Appendix (available with the full text of this article at NEJM.org). Network analysis was performed with the Network program, version 4.5.0.0 (www.fluxus-engineering.com), which uses the median-joining method. The ancient haplotype was determined with the use of the dbSNP database (www.ncbi.nlm.nih.gov/projects/SNP/). Various analyses were conducted, with weighting applied separately for synonymous changes, non-synonymous changes, transitions, and transversions.

MODELING OF DECTIN-1 STRUCTURE
The crystal structure of mouse dectin (Protein Data Bank code 2cl8) was used as a template to build a homology model of the extracellular domain of human dectin-1. Modeling of the extracellular domain was performed on the “WHAT IF” server (http://swift.cmbi.ru.nl). Energy minimization and analysis were performed, to obtain the most reliable model of protein folding, with the YASARA program (www.yasara.org).

FLUORESCENCE-ACTIVATED CELL SORTING
Human peripheral-blood mononuclear cells (PBMCs) were obtained from the three family members who were homozygous for a dectin-1 mutation, the two family members who were heterozygous for a dectin-1 mutation, and five persons who were homozygous for the wild-type dectin-1 allele. The cells were incubated with murine anti–dectin-1 monoclonal antibody GE2 (5 μg per milliliter) or isotype-control antibody, followed by allophycocyanin-conjugated goat antimouse antibody (Pharmingen). Dectin-1 expression was determined by means of flow cytometry with the use of a fluorescence-activated cell sorter (FACSCalibur, BD Biosciences). Dectin-1 expression was assessed in cells from a mouse embryonic fibroblast cell line (NIH3T3) after transfection, with the use of an antihemagglutinin antibody (Covance), an IgG1 isotype-control antibody, and an antimouse antibody covalently labeled with R-phycocerythrin (Jackson ImmunoResearch).
CANDIDA BINDING, PHAGOCYTOSIS, AND FUNGAL-KILLING ASSAYS

Binding of PBMCs to *C. albicans* yeast cells was measured by means of flow cytometry. The phagocytosis and fungal-killing assays for *C. albicans* were performed as previously described.

CYTOKINE MEASUREMENTS

PBMCs (5×10⁶) were incubated with 100 μl of β-glucan (10 μg per milliliter) and *C. albicans* that was live or had been heat-killed (through heating for 30 minutes at 56°C) at a concentration of 1×10⁶ yeast cells per milliliter. For interleukin-17 stimulation assays, PBMCs were stimulated for 5 days in RPMI medium supplemented with 10% pooled human serum. After 4 hours, 24 hours, or 5 days of incubation at 37°C, supernatants were collected and stored at −70°C until enzyme-linked immunosorbent assay with the PeliKine-Tool set of reagents (Sanquin).

CLONING AND TRANSFECTION STUDIES

The human dectin-1 isoforms were amplified, by means of a polymerase-chain-reaction (PCR) assay, from complementary DNA isolated from samples of peripheral-blood leukocytes obtained from the patients. The two primers used were 5′-AAA-GGATCCAGGGGCTCTCAAGAAATG-3′ and 5′-AAACTGAGTCTTCACCCCTTCCCCTAC-3′. The PCR products were purified with the use of the QIAquick PCR purification kit (Qiagen), cloned into the pCR4-TOPO3.1 vector (Invitrogen), and sequenced. The wild-type and mutant dectin-1 were cloned with the use of reverse primers — 5′-CCCTTCCTCGAGCATTGAAAACTTC-3′ and 5′-AAATCTGAGTGGCGAGACTAC-3′, respectively — allowing for the in-frame cloning of a hemagglutinin tag, which does not affect β-glucan binding. The products were subcloned into the retroviral vector pFB-Neo (Stratagene) and transfected into ecotropic packaging cells (Phoenix) with the use of FuGENE transfection reagent (Roche Molecular Biochemicals). After 48 hours, retroviral supernatants were harvested and used to transduce NIH3T3 cells in the presence of Polybrene (Sigma), at a concentration of 5 μg per milliliter. A binding assay for zymosan was also performed, as previously described.

RESULTS

PATIENTS AND PEDIGREE

During the first phase of the screening, we identified a patient (the index patient) who had recurrent vulvovaginal candidiasis and had cells that were hyporesponsive to *C. albicans* stimulation, defined as cytokine production that was 15% or less of that stimulated by *C. albicans* in cells from healthy volunteers. The lack of cytokine production was pinpointed to an impaired response to β-glucan, indicating a potential defect in dectin-1 recognition.

To test this hypothesis, we sequenced the dectin-1 gene in the patient. All six exons of dectin-1 gene, and the nearby intronic regions, were sequenced (see Table 1 in the Supplementary Appendix). We identified a homoygous SNP in exon 6 that caused a change of amino acid 238 from tyrosine to a stop codon (Tyr238X), leading to the loss of the last nine amino acids of the cytoplasmic tail and TM the transmembrane region. Cyto denotes the cytoplasmic tail and TM the transmembrane region. Panel B shows the genetic pedigree of the index family with dectin-1 deficiency. Circles indicate female patients; the square indicates the father. Solid symbols denote homozygosity for the mutation (X/X, seen in all three daughters), and half-solid symbols denote heterozygosity (X/Tyr, seen in the parents).
tyrosine to a stop codon (Tyr238X), leading to the loss of the last nine amino acids of the carbohydrate-recognition domain (Fig. 1A). Additional clinical questioning revealed that one of the patient’s two sisters also had recurrent vulvovaginal candidiasis and both sisters had onychomycosis. The mother of the patient also had chronic onychomycosis, whereas the father had only transient onychomycosis, with a relatively late age at onset and a complete recovery. The nucleotide sequence of wild-type dectin-1 in one healthy volunteer and the nucleotide change (A→C) in exon 6 in two persons who were heterozygous or homozygous for the stop mutation are shown in Figure S3A in the Supplementary Appendix.

The clinical characteristics of the patients are presented in Table 1. Microbiologic assessment of the nails of the three patients who were homozygous for the dectin-1 mutation revealed growth of Trichophyton rubrum. The patients had no known predisposing factors, such as diabetes mellitus or infection with the human immunodeficiency virus. Genetic analysis revealed that both sisters of the patient were homozygous for the Tyr238X mutation, whereas the parents were heterozygous (Fig. 1B). The family members were white persons of Dutch ancestry, according to self-report, and the parents were not known to be related. Investigation of the human dectin-1 protein structure containing the early stop codon (Fig. S3B in the Supplementary Appendix) revealed that a cysteine disulfide bridge between the helix and the deleted strand was absent, a finding likely to have important functional consequences.

**IMMUNOLOGIC DEFECTS**

In the patients who had the early-stop-codon mutation, both monocytes (Fig. 2A) and macrophages (not shown) had significant defects in the production of interleukin-6 after stimulation with β-glucan for 4 hours (P=0.04 for monocytes). Similar defects were apparent after stimulation of cells with either heat-killed or live C. albicans yeast (Fig. S1A in the Supplementary Appendix). The cytokine response was also defective after 24 hours of stimulation with heat-killed C. albicans hyphae (with a 25% reduction of tumor-necrosis-factor production and a 34% reduction of interleukin-6 release). In addition, cells from dectin-1–deficient patients had a marked reduction in interleukin-17 production as compared with cells from persons with the dectin-1 wild-type allele (Fig. S4A in the Supplementary Appendix). Heterozygotes had intermediate production of proinflammatory cytokines on stimulation with C. albicans or β-glucan. In contrast, the response of the patients’ cells to TLR stimuli, such as lipopolysaccharide or lipopeptides, was normal (Fig. S1B in the Supplementary Appendix). In addition, the amplification effect of the interaction between β-glucan and dectin-1 on TLR2 stimulation of cytokines was absent in persons who were homozygous for the mutation (Fig. S1C in the Supplementary Appendix).

To demonstrate that the defect in β-glucan recognition in the patients was indeed due to the truncated dectin-1 variant, we constructed vectors for both wild-type and mutated isoforms A and B of dectin-1 and transfected them into NIH3T3 cells. These experiments revealed that neither mutated isoform A nor mutated isoform B could mediate β-glucan binding, in contrast to the wild-type receptors (Fig. S4B in the Supplementary Appendix). Moreover, although the wild-type dectin-1 isoforms A and B were normally expressed, the mutated isoforms were associated with sig-
significantly lower expression on the cell surface of the transfected cells (Fig. S4C in the Supplementary Appendix).

The in vitro data were corroborated in freshly isolated cells from the patients bearing the stop-codon mutation. Messenger RNA production by cells with the dectin-1 isoforms was similar in persons who were homozygous for the wild-type allele and the patients who were homozygous for the stop mutation (Fig. S4D in the Supplementary Appendix). In contrast, monocytes and neutrophils from the patients who were homozygous for the stop codon lacked cell-membrane expression of dectin-1 (Fig. S4E in the Supplementary Appendix). Heterozygotes had intermediate expression of dectin-1.

The binding of heat-killed fluorescence-labeled C. albicans, which has high levels of β-glucan,22 to monocytes was significantly lower in the patients who were homozygous for the mutation than in healthy controls (Fig. 2B). However, phagocytosis of live C. albicans was normal in both monocytes and neutrophils from the patients who were homozygous for the stop codon (Fig. S2 in the Supplementary Appendix), showing the importance of alternative receptors for phagocytosis of live yeasts (other lectinlike receptors and TLRs).4 Monocytes and neutrophils from the patients who were homozygous for the mutation were as effective at killing C. albicans as were cells from normal persons (Fig. S2 in the Supplementary Appendix).

FREQUENCY OF THE MUTATION IN POPULATIONS

To determine whether the dectin-1 stop mutation was occurring in a phylogenetically conserved site, we compared the amino acid sequence of dectin-1 among several mammals (Fig. S5A in the Supplementary Appendix). This investigation revealed that the mutation lies in an evolutionarily conserved region within the mammalian lineage. We then investigated the prevalence of the mutation in various human populations, and we genotyped persons from four cohorts of healthy persons of various ethnic groups, each representing populations from the major continents: 138 whites of Dutch ancestry (Europe), 99 people from Tanzania (Africa), 100 Han Chinese (Asia), and 105 Trio Indians (Native Americans) from Surinam (South America). Dectin-1 was sequenced completely in the Dutch population, with Tyr238X being the only nonsynonymous mutation identified. The Dutch population had an allele frequency of 0.069, and the Tanzanian population, 0.035; all persons with the mutation were heterozygotes. The mutation was absent in the populations from China and Surinam. This variant has been recorded in the dbSNP database, as rs16910526.

A Human Genome Diversity Project selection browser was used to obtain further information about the frequency and world distribution of the SNP; this analysis confirmed our findings (Fig. 3). We analyzed haplotype diversity within a white population and a black population by studying from the patients who were homozygous for the stop-codon polymorphism lacked cell-membrane expression of dectin-1 (Fig. S4E in the Supplementary Appendix). Heterozygotes had intermediate expression of dectin-1.
Defective surface expression of dectin-1 due to the Tyr238X polymorphism results in lack of β-glucan recognition and an impaired cytokine response by monocytes and macrophages but normal killing of C. albicans by neutrophils. These data show the important role of β-glucan–dectin-1 pathways for normal activation of the cytokine response, 23
but also show the redundant nature of dectin-1 in the phagocytosis and killing of Candida albicans. The normal function of neutrophils in persons in whom dectin-1 function is absent provides protection against invasive fungal infection. In contrast, the defective function of monocytes and macrophages with regard to cytokine release in the patients who were homozygous for the Tyr238X dectin-1 mutation is the most likely cause of the clinical phenotype characterized by mucocutaneous fungal infections.

Dysregulation of cytokine profiles is typically seen in patients with mucocutaneous fungal infections such as recurrent vulvovaginal candidiasis. Dectin-1 is expressed on epithelial cells, and proinflammatory cytokines have been reported to be secreted by vaginal epithelial cells and to increase the natural antifungal activity of these cells. It is therefore conceivable that dectin-1 function on epithelial cells would also be defective in our patients. Our data showing that a complete deficiency of dectin-1 is accompanied by mucosal fungal infections are in line with a recent study showing the susceptibility of dectin-1 knockout mice to mucosal candidiasis.

Dectin-1 is also important for the development of the responses of type 17 helper T cells, and interleukin-17 production in our patients with defective dectin-1, as compared with healthy subjects, was reduced by 50% to 80% (Fig. S4A in the Supplementary Appendix). A clinical syndrome that closely resembles the syndrome in our family, with regard to fungal complications, is the hyper-IgE syndrome. Patients with the hyper-IgE syndrome have a defect in interleukin-17 production in response to infections with Staphylococcus aureus (cutaneous and pulmonary infection) and C. albicans (onychomycosis and mucosal infection). Our family had an isolated interleukin-17 defect in response to C. albicans stimulation, and it is tempting to speculate that this is the cause of the clinical picture of fungal infections in the patients. Our findings are strengthened by the description in this issue of the Journal of a family with a mutation of CARD9, the adaptor molecule for dectin-1, who presented with a phenotype practically identical to that of our family.

Finally, the finding of this dectin-1 mutation in persons from both Europe and Africa leads to additional hypotheses. First, the identification of this polymorphism in all African populations assessed (including the San population) suggests that this is an ancient mutation that most likely emerged more than 60,000 years ago, before the split of the modern human populations in the late Paleolithic. This hypothesis is supported by the finding that the location of the haplotypes containing the Tyr238X mutation was close to the ancient haplotype. Second, the relatively high prevalence of the polymorphism in these populations may represent an important genetic susceptibility factor for mucosal fungal infection.
